Chapter 95

Disorders of the Large Intestine

Michael A. Peterson

IRRITABLE BOWEL SYNDROME

Perspective

Irritable bowel syndrome (IBS) is a chronic non–life-threatening disorder characterized by abdominal pain and alteration in bowel habits. IBS is an extremely common disorder; estimates put the prevalence in the North American population at 10 to 15%, with women affected twice as often as men.[1,2] Although only one third of patients who have the clinical syndrome ever seek medical attention, IBS accounts for more than 10% of all visits to primary care physicians and more than 25% of all visits to gastroenterologists. IBS is said to contribute more impairment to quality of life than either diabetes or renal failure.

No specific physical or laboratory abnormalities defining IBS have been identified. IBS is a functional somatic syndrome that is diagnosed by clinical criteria in the absence of "alarm" symptoms and findings that suggest other, more urgent diagnoses. Diagnosing IBS is problematic in the emergency department (ED), and typically patients are discharged with a diagnosis of "abdominal pain of unclear cause" or the equivalent. Patients with known IBS who are experiencing acute symptoms may also pose a diagnostic challenge. Symptoms of IBS overlap with those of other conditions, including some that are life-threatening, which must be excluded before hospital discharge.

Principles of Disease

Although the cause of IBS is unknown, it is associated with several pathophysiologic findings suggesting that it is a disorder of altered gut motility, gut sensation, and perception of intestinal activity. IBS was originally thought to be primarily a psychiatric disorder because there are no visible anatomic abnormalities and because stress is an exacerbating factor. Physiologic testing has since shown that patients with IBS have disturbances in the rhythmic pattern of electrical activity in the intestine and in how the intestine responds to stimulation. Patients with IBS seem to be more attuned to activity in the abdomen as well, sensing different phases of intestinal motor activity and intestinal content movement to a greater extent than people without IBS.

Psychiatric conditions often coexist with IBS, ranging from generalized anxiety disorder to major depression. IBS has been associated with fibromyalgia, chronic fatigue syndrome, and chronic pelvic pain.[2] An association with previous sexual abuse also has been reported. In women, symptoms often are related to the menstrual cycle, suggesting a hormonal influence. A familial predisposition for the symptoms of IBS has been described, suggesting a genetic component. Bacterial overgrowth and infection have also been associated with IBS.[2]

Clinical Features

The diagnosis of IBS is defined by clinical criteria in a patient whose symptoms have no other organic explanation. Several sets of clinical criteria have been published, one set of which is the Rome III criteria (Box 95-1). Patients with IBS experience symptoms intermittently, with the typical patient averaging symptoms on 1 of every 3 days. Complaints include abdominal pain, bloating, and constipation or diarrhea. Pain typically is relieved with defecation; pain that persists suggests another diagnosis. A mucoid discharge from the rectum often accompanies diarrhea. Upper gastrointestinal symptoms such as nausea and dyspepsia can also occur. Patients may come to the ED with an exacerbation of their previous symptoms or with a new abdominal complaint and often report that they are undergoing a period of stress. Physical examination may reveal either mild focal abdominal tenderness that can vary in location, or diffuse tenderness. IBS is subdivided into three categories: constipation-predominant (IBS-C), diarrhea-predominant (IBS-D), and mixed pattern (IBS-M).[2]

Pain that is progressive or is associated with anorexia or significant abdominal tenderness suggests an alternate diagnosis. Signs and symptoms that point away from the diagnosis of IBS (alarm symptoms) include onset of symptoms after age 50, unintentional weight loss, anorexia, bloody stools, nocturnal diarrhea, or a family history of significant colon disease.[2] In the absence of symptoms suggesting another diagnosis, the clinical criteria have a specificity ranging from 87 to 100%, although sensitivity may be only 60%. In patients determined to have IBS through correct use of the clinical criteria, follow-up evaluation over many years rarely leads to a change in the diagnosis.[2]

A final diagnosis of IBS usually is made in the primary care setting and not in the ED. Studies that are sometimes performed in the evaluation for IBS may include a complete blood count, thyroid studies, stool examination for ova and parasites, evaluation for lactose intolerance, and possibly lower gastrointestinal endoscopy, although current approaches try to limit testing in cases in which the clinical picture is clearly IBS.[3] The ED evaluation seeks to exclude other, more urgent causes for the patient's symptoms. In this setting, testing for pancreatitis, hepatitis, biliary colic, or urologic disorders, including urolithiasis, may be appropriate as indicated by the pattern of the presenting complaints.

Diagnostic Strategies

No specific testing should be done in the ED on individuals who fit the pattern of IBS. In the primary care setting patients may benefit from lactose intolerance or celiac disease testing. Other tests, including colonoscopy, are not found to be helpful.

www.ketabpezeshki.com 66485457-66963820

Box 95-1 Rome III Criteria for Irritable Bowel Syndrome

Recurrent abdominal pain or discomfort at least 3 days per month in the previous 3 months associated with two or more of the following:

1. Improvement with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

From Kahn S, Chang L: Diagnosis and management of IBS. Nat Rev Gastroenterol Hepatol 7:565-581, 2010.

Box 95-2 Differential Diagnosis in Irritable Bowel Syndrome

Constipation—Predominant
Bowel obstruction
Cancer
Adult-onset Hirschsprung's disease
Rectocele
Paradoxical closure of the anus during defecation

Diarrhea—Predominant
Bacterial or parasitic intestinal infection
Inflammatory bowel disease
Lactose intolerance
Malabsorption
Radiation proctocolitis

Painful
Inflammatory bowel disease
Ureteral colic
Bowel obstruction
Diverticular disease
Gastroesophageal reflux or ulcer
Liver or pancreatic disease
Lead toxicity
Porphyria

Differential Considerations

The differential diagnosis of symptomatic IBS depends on the predominant symptoms and includes a host of disorders (Box 95-2). Patients may report pain, constipation, or diarrhea or any combination of the three.

Management

Not all patients with IBS require treatment. It is recommended that therapy be initiated only if symptoms diminish the quality of life.[1] Because no curative therapy is available, treatment is directed toward the relief of symptoms. Diet, behavioral, and pharmacologic therapies all are used in IBS. Specific therapy will be determined by the type of IBS: IBS-C, IBS-D, or IBS-M. Dietary suggestions include a low-fat diet, reduced nondigestible sugars, and avoidance of gas-forming foods, although none of these has any proven benefit. Fiber supplementation may aid IBS-C.

Medications with antispasmodic activity, such as anticholinergics and calcium channel blockers, are used for abdominal cramping, and peripherally acting narcotics, such as loperamide, are used to reduce diarrhea. Osmotic laxatives such as lactulose sometimes are helpful in constipation. Tricyclic antidepressants have been effective in certain classes of patients with IBS. Serotonin receptor antagonists, serotonin receptor agonists, chloride channel activators, and prokinetic agents also are used (Box 95-3), but the serotonin receptor drugs have significant side effects, including adverse cardiovascular events and ischemic colitis, and thus are reserved

Box 95-3 Medications Used in the Treatment of Irritable Bowel Syndrome

Osmotic laxatives
Antidiarrheals
Antispasmodics (anticholinergics and calcium channel blockers)
Tricyclic antidepressants
Serotonin receptor agonist (e.g., tegaserod)
Serotonin receptor antagonists (e.g., alosetron)
Chloride channel activators (e.g., lubiprostone)
Prokinetic agents
Female hormone–modulating agents
Tranquilizers
Rifaximin

for patients with severe symptoms unresponsive to other agents. Nonsteroidal anti-inflammatory drugs (NSAIDs) may worsen symptoms.[3]

Behavioral therapy may benefit patients who are unresponsive to medication, but high-quality evidence of its effectiveness is lacking. A role for nontraditional therapies such as arrowroot, artichoke leaf, and some Chinese traditional herbal medicines is supported by limited scientific evidence.

Disposition

IBS is not a life-threatening disease and can be managed on an outpatient basis as long as other disorders have been excluded. The search for optimal therapy usually involves empirical trials until the correct fit is found. This process is best accomplished through a well-established primary care relationship. The disorder is chronic, but with appropriate therapy, many patients experience significant improvement in their quality of life.

DIVERTICULAR DISEASE

Perspective

Diverticular disease is an affliction of middle age that seems to be a direct consequence of the diet of modern Western civilization. Diverticular disease was virtually unknown in the Western world before the 20th century and is still rare in other cultures. In 1925 only 9% of people older than 50 years of age in the United States had diverticula; by 1968 the percentage had increased to 30%.[4] Today it is estimated that 5 to 10% of people older than 45 years and 80% of people older than 85 years have diverticula. Diverticula are less common in people younger than age 40, representing only approximately 2 to 5% of all patients with the disease. The proliferation of this disease was coincident with the invention and widespread use of the flour rolling mill, which removes the fiber-containing outer part of the wheat kernel. This coincidence has prompted the labeling of diverticulosis as a "modern deficiency disease," which is supported by the fact that adding fiber back into the diet seems to be protective against the development of diverticulosis.[4] In rural Africa and Asia, where the diet is high in fiber, diverticular disease is virtually unknown. Over the last decade the incidence of diverticulitis has increased in the United States, especially in people aged 18 to 44.[5]

Diverticulosis denotes the presence of diverticula in the colon. Most patients with this condition are asymptomatic. *Diverticulitis* denotes inflammation of diverticular tissue, which is usually painful. It is estimated that 10 to 25% of patients with diverticulosis will develop diverticulitis.[5] *Complicated diverticulitis* is defined by the presence of more extensive disease, including abscess formation, peritonitis, intestinal obstruction, or fistula formation.

www.ketabpezeshki.com 66485457-66963820

Principles of Disease

The wall of the colon is penetrated at regular intervals by blood vessels, collectively known as the *vasa recta,* that supply the internal intestinal layers. The site of vessel penetration is apparently the weakest part of the colon wall because it is at these sites that diverticula form. Although the exact pathogenic mechanism is unknown, the current theory is that diverticula form in response to increased intracolonic pressures generated when the colon is processing smaller, non–fiber-containing stools. Patients with diverticular disease exhibit normal resting colonic pressure but higher peak pressure than those without diverticular disease[5]; higher peak pressures lead to a herniation of colonic mucosa through the intestinal wall at the vasa recta, creating small, saclike appendages. These appendages (diverticula) typically measure 5 to 10 mm in diameter but on rare occasions can grow into huge sacs measuring many centimeters across *(giant colonic diverticula).* Diverticula are generally asymptomatic; symptoms are believed to develop when diverticula become obstructed, presumably with inspissated stool. When obstruction occurs, inflammation sets in and microperforations of the sac develop, resulting in inflammation of pericolonic structures and abdominal pain.

In the Western world, most diverticular disease occurs in the left colon, usually the sigmoid. This is not the case in Japan, where right-sided diverticular disease is more common. Japanese-Hawaiians consuming a low-fiber Western diet have a significantly increased incidence of diverticular disease, but it remains in the right colon.[4] This finding suggests that although diet plays a significant role in the formation of diverticula, the location of diverticula is genetically determined.

A spectrum of disease is observed in relation to diverticular inflammation. In *uncomplicated* diverticulitis, only the pericolonic fat is inflamed. With time, a phlegmon, abscess, or gross perforation may develop. Any extension of disease beyond the pericolonic fat is considered to represent *complicated* diverticulitis. The involved colonic segment may fistulize to any adjacent organ, most commonly the bladder. Adjacent bowel may become obstructed by mass effect from an abscess or may incur an inflammatory ileus. Recurrent episodes of diverticulitis can lead to strictures in the colon with subsequent colonic obstruction.

Diverticula can also bleed, presumably from erosion into the mucosal wall by dried stool trapped in the diverticular sac. Severe hemorrhage occurs in 3 to 5% of all patients with diverticulosis and accounts for approximately 40% of all instances of lower gastrointestinal hemorrhage.[4] Bleeding notably occurs in the absence of inflammation and typically is painless. NSAID use is associated with this complication.

Clinical Features

Diverticulosis

Although approximately 75% remain asymptomatic throughout their lifetime,[4,6] patients with diverticulosis sometimes have nonspecific abdominal complaints including bloating, crampy pain, excessive gas, or a change in bowel habits.[7] Diverticulitis will develop in approximately 10 to 30% of patients with diverticulosis.

Diverticulitis

Because most diverticula found in persons in the Western world form in the left colon, the typical presentation of diverticulitis is persistent left lower quadrant pain and tenderness. Pain may be felt first in the hypogastrium before localizing to the left lower quadrant. Referred pain may occur in the penis, scrotum, or suprapubic region. Right-sided diverticulitis may manifest as right lower quadrant pain and is impossible to distinguish clinically from appendicitis. Additional findings suggest various complications: diffuse tenderness is associated with gross perforation or abscess rupture; dysuria, with a colovesical fistula; mass, with an abscess; and vomiting or abdominal distention, with intestinal obstruction. Fecal matter or gas emanating from the vagina suggests a colouterine fistula. Almost any adjacent organ can be involved in the inflammatory process. Patients recently diagnosed with diverticulitis who are being treated on an outpatient basis with oral antibiotics and who visit the ED with continuing or worsening symptoms should be evaluated for the possibility of an abscess.

Special care must be taken with elders or immunocompromised patients because clinical signs and symptoms are much less dramatic, even with more severe disease. Perforation is more common in these patients (up to 40%), manifests with less significant findings, and carries a high mortality rate.[5]

Diagnostic Strategies

Uncomplicated Diverticulitis

The clinical diagnosis of uncomplicated diverticulitis can be made in a patient in the appropriate age range exhibiting focal left lower quadrant pain and tenderness in the absence of symptoms or signs that suggest an alternative diagnosis. No mass or peritoneal irritation should be encountered on examination, and the patient should otherwise appear well. If the patient fits this clinical picture, treatment can be initiated on an empirical basis, and no laboratory tests or diagnostic imaging is required. Ancillary tests are performed primarily to exclude alternative diagnoses or the presence of complicated diverticulitis. When the diagnosis is unclear, studies to exclude gynecologic, renal, hepatic, biliary, or pancreatic disease may be indicated, depending on the patient's presentation and degree of distress. Computed tomography (CT) of the abdomen should be considered for elders and immunocompromised patients to exclude the possibility of a subtle presentation of complicated diverticulitis.

Complicated Diverticulitis

Abdominal Computed Tomography. Abdominal CT is the preferred method of evaluation in complicated diverticulitis. CT has the advantage of evaluating the colon and the structures around it, so it can facilitate the diagnosis of diverticulitis and simultaneous evaluation of the extent of disease. CT can also be used to guide percutaneous drainage of diverticular abscesses. Findings on CT consistent with diverticulitis include the presence of diverticula, inflammation of pericolonic fat, thickening of the bowel wall to more than 4 mm, free abdominal air, and abscesses.[6,8] CT also can help make an alternative diagnosis when diverticulitis is absent. CT is relatively noninvasive and is well tolerated by ill patients. Sensitivity and specificity for diverticulitis range from 69 to 95% and from 75 to 100%, respectively.[8] Negative findings on CT scan cannot absolutely exclude diverticulitis. Small abscesses within the colon or mesocolon can be missed, as can the diverticula themselves. It may also be difficult to differentiate between carcinoma and diverticulitis on CT scan. Marked bowel wall thickening associated with diverticulitis looks like cancer; contrast enema or endoscopy may be required to differentiate the two.

Barium Enema. Although double-contrast barium examination is the standard for the diagnosis of asymptomatic diverticula, it should be avoided in the setting of diverticulitis. The potential for preexisting occult perforation and subsequent risk of barium

www.ketabpezeshki.com 66485457-66963820

peritonitis limits its usefulness. Barium enema may be used after the acute episode to exclude the diagnosis of carcinoma.

Water-Soluble Contrast Enema. Although now rarely used, a water-soluble contrast enema is the preferred method of imaging if a contrast enema study is needed in the acute setting. Water-soluble contrast material shows less detail than barium, but this modality is still useful. Findings consistent with diverticulitis include the presence of diverticula along with extravasation of contrast material into an abscess cavity or into the peritoneum. This study can also show a fistula or evidence of compression of the colon by an extrinsic mass. Because contrast material usually collects only in the intestinal lumen, contrast enemas give less information than CT about the extent of disease outside of the colon.

Ultrasonography. Ultrasound examination can detect various pathologic features characteristic of diverticulitis, including fluid collections around the colon, thickened hypoechoic bowel wall, or hyperechoicity adjacent to the bowel wall that suggests pericolonic inflammation. Tenderness to palpation over an abnormal-appearing colon suggests that the colon is the source of the patient's pain. Diverticula can occasionally be visualized by ultrasound examination. As is often the case, the sensitivity of ultrasound imaging for these findings varies significantly with the experience of the operator. Because gas interferes with ultrasound imaging, adequate visualization of the bowel can be a problem. Currently, the role for ultrasonography in the evaluation of diverticulitis is not well defined.

Endoscopy. Endoscopy is limited in the acute setting by its more invasive nature, the risk of perforation, and the logistics of arranging this procedure emergently.[9,10] Although the endoscope affords visualization of diverticula and other pathologic processes within the lumen of the colon, it does not permit evaluation of the extent of extracolonic disease.

Plain Radiography. Plain radiographs of the abdomen are not likely to be helpful in the diagnosis of diverticulitis unless either intestinal obstruction or perforation is suspected.

Differential Considerations

In a patient with more serious disease, making the correct diagnosis usually poses no great dilemma because more extensive laboratory testing and diagnostic imaging typically have been performed. In a patient with milder disease, in whom a tentative diagnosis of diverticulitis may be based on clinical grounds alone, the differential diagnosis presents more of a challenge. An important consideration is whether or not the patient has colonic carcinoma; however, it usually is safe to wait until after the acute episode has resolved to investigate this possibility. Additional diagnoses to consider include colitis (either inflammatory or ischemic); ureteral stones; inguinal hernia; and pelvic pathology, including ectopic pregnancy or pelvic inflammatory disease, and ovarian pathology with or without ovarian torsion. Appendicitis should be suspected when symptoms are predominantly right sided. Diffuse abdominal pain should prompt an evaluation for other life-threatening problems, including leaking abdominal aortic aneurysm, peritonitis, hemoperitoneum from ectopic pregnancy, and bowel obstruction.

Management

Diverticulosis

All patients diagnosed with diverticulosis should be placed on a high-fiber diet, which has been shown to reduce abdominal symptoms and recurrent bouts of diverticulitis. The common advice to avoid foods that may obstruct diverticula, such as nuts, small seeds, and popcorn, has recently been discredited.[5]

Box 95-4 Oral Antibiotic Therapy for Uncomplicated Diverticulitis

- Trimethoprim-sulfamethoxazole, one double-strength tablet bid, *and* metronidazole 500 mg q6h *or*
- Ciprofloxacin 750 mg bid *and* metronidazole 500 mg q6h *or*
- Amoxicillin-clavulanate extended-release, 1000/62.5 mg, two tablets bid

All oral regimens should be taken for 7 to 10 days.

IV, intravenously.

Uncomplicated Diverticulitis

Uncomplicated diverticulitis in an immunocompetent, nonelderly patient can be managed on an outpatient basis with oral antibiotics[11] (Box 95-4). Coverage for gram-negative aerobic and anaerobic bacteria is required. Patients may be placed on a liquid diet for comfort, although this is not mandatory. NSAIDs or narcotics are appropriate for pain control, but many experts recommend avoiding morphine sulfate because it increases intraintestinal pressure, which can theoretically precipitate perforation. A high-fiber diet prevents recurrent diverticulitis for 5 years in 70% of patients.

Patients with significant comorbid illness or other problems, including inability to tolerate oral liquids, poor social support, and inability to comply with follow-up in a reasonable time frame (2 to 3 days), should be considered for hospital admission. Hospitalized patients generally are treated with intravenous antibiotics (Box 95-5) and placed on bowel rest, although patients hospitalized for psychosocial reasons can be treated with oral medications.

Complicated Diverticulitis

Patients with complicated diverticulitis should be admitted to the hospital and treated with intravenous antibiotics and bowel rest. Emergent surgical intervention is indicated for all patients with peritonitis or perforation. Newer techniques that use a laparoscopic approach with lavage and biologic glue have supplanted open surgical techniques in some patients.[12] Continuing clinical decline, sepsis resistant to medical management, or a high level of suspicion for carcinoma warrants urgent surgical consultation.[6] Small abscesses (less than 5 cm in diameter) are treated with intravenous antibiotics alone (see Box 95-5), whereas larger abscesses are drained either percutaneously with imaging guidance or surgically.[13] Bowel obstruction during an attack of diverticulitis usually is self-limited and resolves with conservative management. Chronic recurrent diverticulitis can result in stricture, necessitating surgical intervention. Fistulae are usually repaired surgically

www.ketabpezeshki.com 66485457-66963820

but are typically not emergent.[5] A significantly dilated cecum (to greater than 10 cm in diameter) or gas in the bowel wall should prompt early consultation with a surgeon about the possibility of bowel necrosis and impending perforation.

Definitive Management

It is not known whether medical or dietary treatment is of benefit in diverticulitis. The only proven way to eradicate diverticula is to remove the affected segment of colon surgically. Most patients who recover from their first attack of diverticulitis are likely to remain asymptomatic for many years. With subsequent attacks, the likelihood of recurrence increases. Elective resection of diverticula generally is reserved for patients who have had more than one attack of diverticulitis. According to some experts, younger patients (i.e., younger than 40 years) should undergo elective resection after their first bout of diverticulitis because of concerns about a higher risk for a second attack, but this recommendation is controversial, with recent evidence suggesting that outcomes are better without surgery.[6] Most resections can be done laparoscopically with a single-stage procedure (no colostomy). Estimates on recurrence of diverticular disease after resection vary, ranging from 3 to 27%.[7,14]

Disposition

Uncomplicated Diverticulitis

Nonelderly and immunocompetent patients may be sent home on oral antibiotics with referral for follow-up evaluation in 2 to 3 days to determine the success of treatment. Patients are cautioned to return to the ED if their condition worsens. Patients not significantly improved at follow-up should undergo diagnostic imaging to look for an abscess and should be hospitalized for intravenous antibiotic therapy. Of patients treated medically for their first attack of diverticulitis, 95% remain symptom-free for the next 2 years, and 80 to 90% remain symptom-free permanently.[14] Patients with recurrent episodes of diverticulitis should be referred to a surgeon for outpatient consultation for elective resection. All patients should undergo an evaluation for colon cancer when the acute episode has resolved because the incidence of coexistent cancer has been reported to be as high as 9%.[9]

Complicated Diverticulitis

All patients require hospitalization for intravenous antibiotic therapy and bowel rest. Most patients (65-85%) recover with medical management alone; the rest require surgical intervention. Outcomes generally are good, with mortality rates ranging from 1 to 6% for all patients, increasing to 12 to 18% for patients requiring surgery.[4]

LARGE BOWEL OBSTRUCTION

Perspective

Large bowel obstruction (LBO) is much less common than small bowel obstruction, but LBO is a more ominous condition because it is frequently associated with malignant disease. One half of all operative cases involving LBO in the United States are the result of colorectal cancer, and up to 20% of patients with colon cancer will develop acute obstruction.[15] Adhesions, a common cause of small bowel obstruction, cause only a small number of LBOs. Other causes of LBO include volvulus, diverticular disease, fecal impaction, strictures (often related to inflammatory bowel disease [IBD] or chronic colon ischemia), adhesions, hernia, and pseudo-obstruction. Most causes are managed surgically, but pseudo-obstruction responds well to medical management alone.

Principles of Disease

When mechanical obstruction is secondary to an obstructing lesion, either inside the bowel (carcinoma) or outside the bowel (diverticular abscess, volvulus), the bowel becomes increasingly dilated with air and fluid that cannot be passed distally. As the distention increases, the intraluminal pressure increases. When intraluminal pressure approaches systolic blood pressure, blood flow to the bowel wall is compromised and edema sets in, with subsequent transudation of fluid into the lumen. Transudation along with decreased resorption of intraluminal fluid leads to dehydration. Eventually, as arterial flow to the bowel wall is compromised, ischemia and gangrene develop. Translocation of bacteria from compromised bowel can lead to sepsis. Perforation of the bowel wall follows if the process is not interrupted.

Pseudo-obstruction, also called *Ogilvie's syndrome,* occurs through a completely different mechanism. *Pseudo-obstruction* is defined as LBO in which no obstructing lesion can be identified. This condition usually is found in patients with significant acute comorbid conditions.[16] Patients typically have a history of significant spine or retroperitoneal trauma, severe electrolyte disturbances, or narcotic exposure. Although the exact mechanism is unknown, it is believed to involve malfunction of autonomic control of the bowel. Normal balance between parasympathetic and sympathetic input is disrupted, resulting in changes in motility that lead to obstruction. The pathophysiologic changes observed with pseudo-obstruction are the same as those described for mechanical obstruction.

Clinical Features

The typical presenting complaints in LBO are abdominal pain, abdominal distention, obstipation, and vomiting. The time frame within which these symptoms develop varies in accordance with the rapidity of onset of the obstruction. LBO associated with a volvulus can develop rapidly, whereas obstruction from cancer tends to be of gradual onset. Patients seen later in the course of obstruction may be significantly dehydrated. Significant fever or tachycardia should prompt an investigation for gangrene and perforation. A palpable abdominal mass may represent a tumor, an abscess, or simply distended bowel. A rectal examination is helpful to look for an obstructing rectal mass or a large volume of hard stool in the rectal vault consistent with fecal impaction.

Diagnostic Strategies

Electrolyte measurements may be helpful in guiding fluid and electrolyte replacement therapy. A significantly elevated white blood cell (WBC) count should raise suspicion for gangrenous bowel, whereas anemia suggests the possibility of colorectal cancer.

Plain Radiography

A distended colon is the hallmark of LBO (Fig. 95-1), although small bowel may be distended as well if the ileocecal valve is incompetent. In some cases, gas-filled small bowel may obscure visualization of the colon, leading to the misdiagnosis of small bowel obstruction. An abrupt cutoff at the distal end of the obstructed colonic segment suggests a possible pseudo-obstruction. A cecal diameter exceeding 12 cm is of concern because this finding is associated with a higher risk of perforation.[16] The actual location and cause of the LBO are usually not evident on plain films.

www.ketabpezeshki.com 66485457-66963820

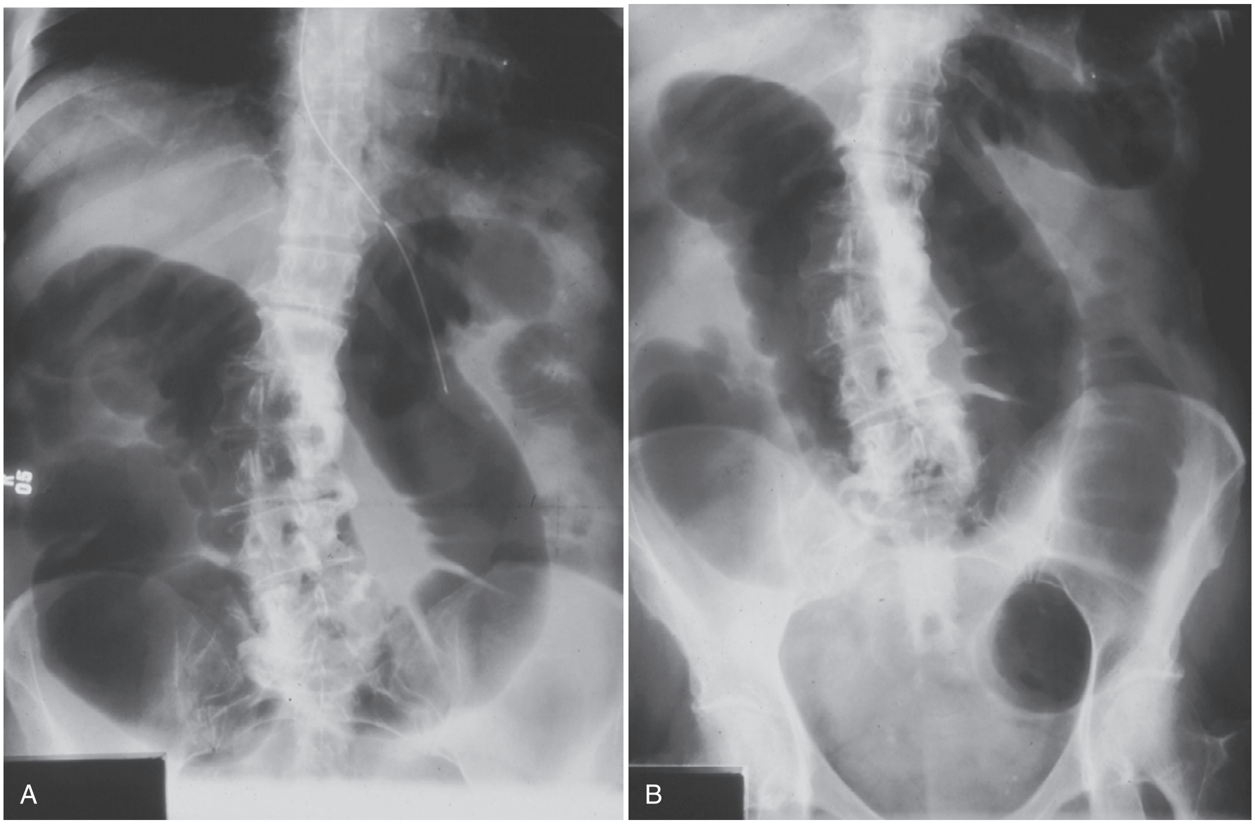

Figure 95-1. Plain radiographs showing large bowel obstruction at the sigmoid colon caused by carcinoma. **A,** Upright view. **B,** Supine view.

Computed Tomography

CT is a valuable tool for determining the cause of the obstruction, especially if the cause is a diverticular abscess or intussusception. CT typically is less helpful in pseudo-obstruction, in which either colonoscopy or a water-soluble contrast enema study is needed to make the diagnosis.

Colonoscopy and Water-Soluble Contrast Enema

Patients in whom the cause of obstruction is not known and who are not candidates for urgent surgical intervention should undergo either a water-soluble contrast enema study or colonoscopy to determine the cause of the obstruction. This diagnostic strategy is much more accurate in ruling out pseudo-obstruction than imaging.

Differential Considerations

The most common causes of LBO are colorectal cancer (53%), volvulus (17%), diverticulitis (12%), and compression from metastatic disease (6%). Other, less common causes are strictures, incarcerated hernia, fecal impaction, adhesions, and pseudo-obstruction.

Management

Management in the ED is directed at relief of symptoms. Rehydration, electrolyte replacement, and pain management are the first concerns. Gastric decompression with a nasogastric tube may be helpful in cases in which vomiting is prominent or when there is evidence of significant fluid or gas buildup in the small intestine. No additional fluid or solids should be administered by mouth. Antibiotics are indicated if gangrene or perforation is suspected (see Box 95-5). Definitive management depends on the cause of the obstruction. Select diverticular abscesses may be drained percutaneously, whereas a sigmoid volvulus or pseudo-obstruction can be decompressed endoscopically. Diverticular disease and sigmoid volvulus eventually necessitate an elective surgical procedure to prevent recurrence, although this often can be delayed. Carcinoma, cecal volvulus, strictures, intussusception, adhesions, and hernias are dealt with primarily surgically. In malignant obstruction of the left colon, placement of a stent can be done palliatively or as a bridge to surgery.[15]

As long as the possibility of perforation is not an immediate concern, pseudo-obstruction is managed for the first 24 hours with bowel rest, hydration, and management of any acute comorbid conditions. If the colon fails to decompress, colonoscopic or pharmacologic intervention (neostigmine) may be attempted, with surgery reserved for refractory cases.[16]

Fecal impaction is generally managed definitively in the ED by digital disimpaction or an enema. Particularly helpful are retention enemas, for which the patient retains the enema fluid in the rectum for 15 minutes or longer. Occasionally, disimpaction is technically difficult enough to warrant general anesthesia.

Disposition

Most cases of LBO require procedural intervention (surgical, endoscopic, or percutaneous abscess drainage) to achieve resolution. All patients require hospitalization and consultation with a specialist capable of performing the appropriate procedure. Emergent surgical consultation is warranted in patients with evidence of gangrenous bowel or perforation.

www.ketabpezeshki.com 66485457-66963820

VOLVULUS

Perspective

Volvulus of the colon occurs when a loop of bowel twists and obstructs the intestinal lumen. If severe enough, the twist may involve and compromise the vascular supply to the loop of colon. The incidence of colonic volvulus is 2.65 cases per 100,000 population per year, accounting for 1 to 7% of all LBOs.[17] Volvulus occurs in all age groups, but older adults are affected most often, with a mean age of 60 to 70 years. One third of cases in the developed world involve institutionalized patients.[17] Most cases are divided roughly equally between the sigmoid colon and the cecum, although volvulus can occur in all other areas of the colon. Sigmoid volvulus typically is a disease of older persons. Mortality rates with sigmoid volvulus exceed 50% in patients with gangrenous bowel. In the absence of gangrenous bowel, the risk of death is less than 5%.[17]

Principles of Disease

Sigmoid Volvulus

The anatomic requirement for a sigmoid volvulus is a long, redundant section of sigmoid that is attached to the abdominal wall by a narrow strip of mesentery. The narrow attachment allows the mesentery to twist on itself, thereby obstructing the intestinal lumen. It is not clear whether this is a congenital condition or occurs as part of the aging process, but the fact that sigmoid volvulus rarely occurs before the third decade suggests it is an acquired condition.[17] After the colon twists on itself, the proximal colon continues to force gas and liquid into the obstructed segment, causing a sometimes massive dilation of the distal colon. Significant electrolyte disturbances can occur secondary to third spacing, and respiratory compromise occasionally occurs from massive abdominal distention. If the condition is left untreated, the vascular supply can become compromised, resulting in gangrene and perforation. In one series, approximately 10% of patients developed gangrene of the affected segment.[18] The exact precipitator of an acute episode of volvulus is not clear. A high-fiber diet has been implicated, because a significant increase in the disease is noted in patients who are switched to a high-fiber diet. Chronic constipation has been associated with volvulus, but it is unclear how the two conditions are related. Residents of long-term care facilities and patients with neurologic or psychiatric diseases also are predisposed to sigmoid volvulus, possibly as a result of alterations in colonic motility. No association with previous surgery has been observed.

Cecal Volvulus

As in sigmoid volvulus, a mobile segment of cecum is a prerequisite to the disease. This mobility seems to be a result of a congenitally incomplete fusion of the cecal mesentery to the posterior abdominal wall. Cadaver studies show that 11 to 25% of the adult population have ceca that are mobile enough to cause torsion.[19] In 10% of the cases, cecal volvulus is a result of a variant called *cecal bascule,* in which the cecum does not twist but merely folds over on itself; symptoms and management are the same. The tendency for cecal volvulus may be related to "maneuvering room" available for the colon within the abdomen. Women seem to be at a higher risk for cecal volvulus during pregnancy, presumably because of crowding of the abdominal cavity by the enlarged uterus. The condition is still rare, however, occurring in approximately one per million pregnancies.[20] Gangrene of the bowel is common with cecal volvulus, occurring in 20% of patients.[18]

Clinical Features

Sigmoid Volvulus

The hallmark of sigmoid volvulus is the triad of abdominal pain, distention, and constipation. The extent to which the sigmoid colon can twist on itself is recognized to vary, so the presentation of sigmoid volvulus will vary accordingly, from subtle to dramatic. The clinical picture may range from one of minor abdominal discomfort that has been present for many days to an acute onset of severe abdominal pain associated with gross abdominal distention and unstable vital signs. Sometimes the diagnosis of sigmoid volvulus is not made until the patient has been hospitalized for some time. In many instances the history may be suggestive of previous episodes of volvulus that self-reduced. Diarrhea may be present in cases with incomplete obstruction.[17]

The physical examination may reveal a distended tympanitic abdomen, often with most of the distention in the upper abdomen but primarily on one side. Patients may look remarkably well for the amount of distention that is encountered. Significant abdominal pain, fever, lack of bowel sounds, peritonitis, or cardiovascular instability suggests gangrenous bowel and should prompt immediate surgical consultation. The absence of these findings does not exclude gangrene, however. The duration of symptoms alone is not predictive of gangrene of the bowel.

Cecal Volvulus

Though the vast majority of patients (90%) have abdominal pain, the clinical triad of abdominal pain, distention, and constipation is inconsistent.[18] Patterns of presentation vary on a spectrum similar to that for sigmoid volvulus.[19] Vomiting is seen in only about 50% of patients.

Diagnostic Strategies

Sigmoid Volvulus

The diagnosis of sigmoid volvulus can be made on the basis of findings on plain radiographs in most cases. A grossly distended loop of colon lacking haustral markings is typical and is seen just as often on the right side of the abdomen as on the left (Fig. 95-2). The bowel may have the appearance of a "bent inner tube." Free air may be seen on an upright chest radiograph or lateral decubitus radiograph of the abdomen in patients who have a perforation. Gas backing up into the rest of the colon may obscure the typical appearance of sigmoid volvulus on plain radiographs, leading to a significant number of nondiagnostic studies. Cecal volvulus and bowel obstruction from other causes may have a similar radiographic appearance. When the diagnosis is in doubt, contrast enema may be helpful. Contrast material fills up the colon to the tapering point of torsion, giving a "bird's beak" appearance to the column of contrast material (Fig. 95-3). Sigmoidoscopy is diagnostic in many cases, visualizing a spiral sphincter-like twist in the colonic mucosa.[21] CT scan, when used, is also highly accurate, but most diagnoses can be made without it.[21,22]

Cecal Volvulus

Plain radiographs often are helpful in establishing a diagnosis of cecal volvulus, but the findings are not definitive in 50% of cases. The cecum should be markedly dilated and may contain an air-fluid level. The small bowel often is distended as well. In contrast with the picture in sigmoid volvulus, the distal colon should have a paucity of gas (Fig. 95-4). The classic "coffee bean" sign, a large oval gas shadow with a line down the middle representing bowel bent over on itself, may be seen in the midabdomen. Free

www.ketabpezeshki.com 66485457-66963820

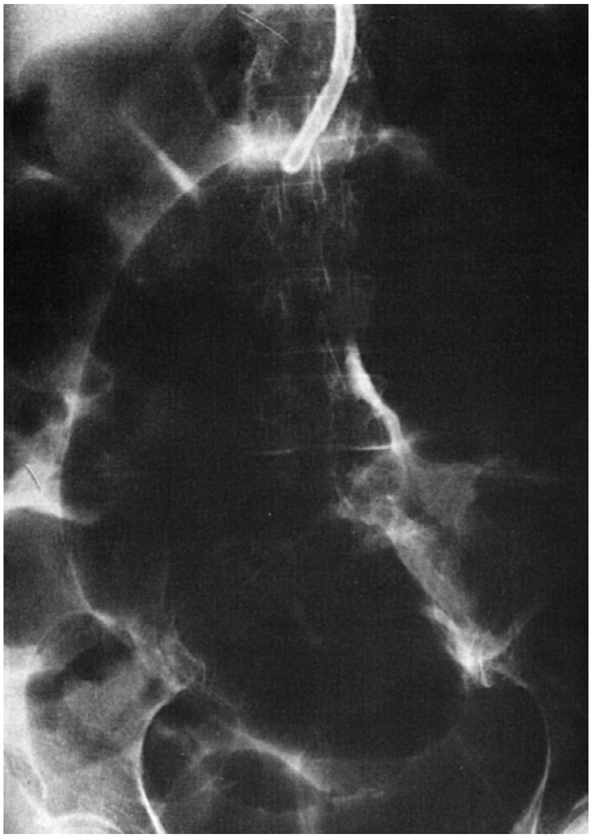

Figure 95-2. Plain film of abdomen shows a large dilated loop characteristic of sigmoid volvulus.

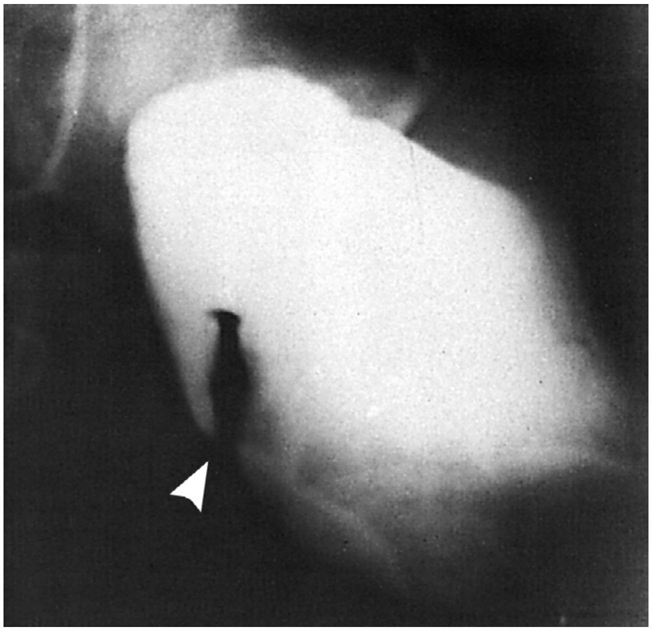

Figure 95-3. Characteristic "bird's beak" sign of volvulus *(arrowhead)* shown on this image from a barium enema study.

air suggests perforation and necessitates emergent surgical consultation. A common mistake is misinterpreting the plain radiograph as showing a sigmoid volvulus. If the diagnosis is unclear, a contrast enema is helpful in showing the site of torsion. Ultrasound imaging generally is unhelpful.[20] On CT, a mesocolon "whirl sign"

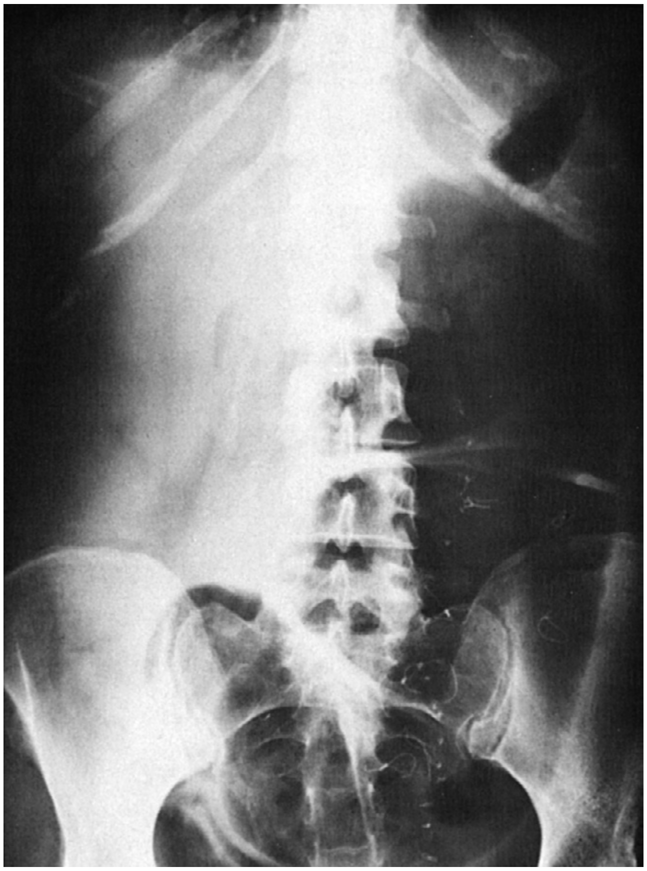

Figure 95-4. Plain radiograph shows distended colon characteristic of cecal volvulus. Note presentation in the left lower quadrant and absence of right-sided gas shadows.

may be seen, indicating a twisted segment of mesentery.[23] In many cases, cecal volvulus is definitively diagnosed only at surgery.[18]

Differential Considerations

Any process that causes LBO may mimic volvulus, including neoplastic disease, paralytic ileus, toxic megacolon, and pseudo-obstruction.

Management

Sigmoid Volvulus

Although spontaneous reduction of a sigmoid volvulus can occur, it is infrequent enough to mandate a proactive approach to treatment. If clinical evidence of gangrenous bowel is lacking, endoscopic detorsion should be attempted by an experienced operator. With the endoscope the bowel is first examined for any signs of gangrene. If the bowel is healthy, the twisted, obstructed proximal end of the bowel lumen is identified, and a lubricated flexible tube is inserted through the obstruction. With decompression of gas and liquid stool, the bowel is able to undergo self-detorsion. Endoscopic decompression is successful in 50 to 90% of cases.[21] If the patient has gangrenous bowel or the volvulus does not respond to endoscopic decompression, surgery is indicated. Recurrence rates are estimated at 60%; as a preventative, elective resection of the redundant sigmoid is recommended after resolution of the acute episode. The mortality rate for sigmoid volvulus is 20% overall and exceeds 50% in the subpopulation of patients with gangrene.

www.ketabpezeshki.com 66485457-66963820

Cecal Volvulus

The proximal nature of the cecum makes it unavailable for endoscopic manipulation; cecal volvulus requires resection of the cecum. Recurrence is rare after resection.[19]

Disposition

All patients with volvulus require hospitalization for surgical intervention.

INTUSSUSCEPTION

Perspective

Intussusception in adults is rare, accounting for only 1 to 5% of cases of adult bowel obstruction.[24] Most adult intussusceptions (80%) are of the small bowel. Although only 10% of children have a pathologic lesion as the cause of the intussusception, 90% of adults do. In the colon, these lesions are malignant 50 to 80% of the time, as opposed to in the small bowel, in which malignant lesions are present approximately one third of the time.[25] In adults, the intussusception is often unsuspected before being revealed on a CT scan or during laparotomy. The condition occurs over a wide variety of ages, with a mean age at presentation of 65 years.[26]

Principles of Disease

The exact mechanism of intussusception is unknown, but it is believed that a lesion (the "lead point") changes the motility properties of the intestine, allowing a proximal segment to invaginate into a more distal segment. As peristaltic activity pushes the invaginated segment along with its mesentery and mesenteric blood vessels distally down the bowel, the blood supply to the segment can be compromised, and ischemia may occur. Edema associated with the intussusception can lead to a mechanical obstruction of the bowel. In 8 to 20% of cases no lead point can be identified.[24]

Clinical Features

Intussusception in adults manifests in one of two patterns. The most common is that of acute partial intestinal obstruction. Less than 20% of intussusceptions cause complete obstruction.[27] With this pattern, the typical presenting complaint is abdominal pain. Vomiting, bleeding, and constipation may be present but often are not. The abdomen may be distended, and bowel sounds often are decreased. A mass is seldom palpated; the classic triad of abdominal pain, mass, and heme-positive stools noted in children is rarely found in adults. The second presentation is much more subtle, with intermittent abdominal pain for months or years. The diagnosis usually is made only when the pain becomes unrelenting or has been recurrent enough to prompt imaging.

DIAGNOSTIC STRATEGIES

Plain Radiography

Plain radiography is a reasonable screening test in a patient suspected of having bowel obstruction, but the radiographs usually show only nonspecific large bowel dilation.

Computed Tomography

Typically used in the evaluation of abdominal pain and bowel obstruction, CT is usually the most useful test in suspected intussusception but may not detect the actual intussusception in as many as one half of cases.[25,26]

Ultrasound Examination

Ultrasonography is helpful in detecting intussusception but is not as useful as CT in excluding other diagnoses. A transverse view of the intussusception has a donut or target shape, with multiple concentric rings. A longitudinal view of the intussuscepted segment has an ultrasound appearance similar to that of a kidney ("pseudo-kidney sign"), with a bright central area surrounded by a darker outer layer.

Barium Enema

Although a barium enema study can demonstrate intussusception and even reduce it, it is a less desirable study than either CT or ultrasound examination for initial diagnosis. In contrast to children, reduction of intussusception in adults is not desirable before surgery because of concerns about spreading malignant cells from potentially malignant lead points. Barium enema should not be performed in patients suspected of having a bowel perforation.

Colonoscopy

Colonoscopy is helpful in defining the lesion causing intussusception but does not usually detect the intussusception itself.

Differential Considerations

The differential diagnosis includes other causes of bowel obstruction.

Management

Surgery is required in most cases. ED care is supportive and aimed at optimizing fluid status, recognizing gangrene or perforation, administering antibiotics if compromised bowel is suspected, and securing surgical consultation in the appropriate time frame. Because of the high incidence of malignancy, reduction often is not attempted in adults before surgical exploration.[26] Occasionally, intussusception may resolve spontaneously, but an evaluation to exclude a pathologic lead point must still be undertaken.

Disposition

Because of the surgical nature of this disease, all patients require hospitalization. Operative mortality tends to be minimal.[25]

INFLAMMATORY BOWEL DISEASE

Perspective

IBD includes two clinically similar but distinct diseases: Crohn's disease (CD) and ulcerative colitis (UC). Both diseases are characterized by chronic and unpredictable relapsing inflammation of the gastrointestinal tract from causes that have not been definitively identified. Significant morbidity occurs from acute exacerbations of inflammation. It is estimated that more than 1 million people in the United States are affected by IBD.[25] Cases are divided approximately equally between CD and UC, with a combined annual incidence of approximately 10 cases per 100,000.[29] The long-term management of IBD is a complex, stepwise process that involves multiple medications and surgery. The goals of ED evaluation are to (1) recognize potential new cases of IBD, (2) consider and exclude serious complications in patients with IBD, and (3) identify those patients with IBD who need in-hospital care. Treatment plans are best developed in consultation with a physician experienced in the long-term management of IBD. Although life

www.ketabpezeshki.com 66485457-66963820

expectancy is slightly decreased for patients with CD, it is normal for patients with UC.[30]

Principles of Disease

Ulcerative Colitis

UC causes inflammation and ulceration throughout the colon and rectum but spares the small intestine. Inflammation is more superficial than that found in CD. Typically the inflammation exists as one continuous lesion originating in the rectum and extending a variable distance into the colon, although more recently cases of discontinuous disease ("skip lesions") similar to that in CD have been reported in UC.[31] The concordance rate between identical twins is low (6 to 14%), suggesting that factors other than genetics are involved in the development of UC.[32] Stress can trigger exacerbations, and cigarette smoking has a protective effect, suggesting environmental factors at work. Appendectomy at an early age is protective, suggesting that the immune system may play a role. In animal models of IBD, the disease does not occur in animals that are devoid of normal bowel flora, suggesting that bowel flora are a necessary ingredient for disease.[33] One unifying theory is that UC represents a genetic predisposition for the development of an inflammatory reaction to normal intestinal flora—in essence, loss of the normal tolerance to these bacteria.

Crohn's Disease

The cause of CD is unknown, but genetic, environmental, immunologic, and infectious processes have all been implicated as possible causative or contributory factors.[29] Concordance between identical twins is 45 to 50%, suggesting a strong genetic predisposition that is modified by other factors.[32] Africans have a low incidence of CD, but African Americans have an incidence similar to that in white Americans.[29] The first genetic mutation associated with CD was described in 2001 and is associated with 10 to 20% of cases of CD.[31] Although the onset of the disease can occur at any time of life, CD affects primarily young patients, with onset of disease typically in the teens and 20s. Inflammation in CD is deep, involving the entire colonic wall. The disease is not limited to the colon and rectum as it is in UC but may affect any part of the gastrointestinal tract. CD most often involves the distal small intestine and colon and less commonly the esophagus, duodenum, or stomach. Because of the transmural nature of the inflammation, the development of intestinal strictures or fistulae to adjacent organs is a potential complication.

Clinical Features

Typical presenting complaints in patients with IBD include abdominal pain, often crampy, and tenesmus with loose or diarrheal stools. Blood may be present in the stool. Patients with CD may have a history of nocturnal diarrhea, a complaint that helps differentiate CD from patients who have IBS. Weight loss is common. The physical examination may reveal significant abdominal tenderness or an abdominal mass representing an abscess. Patients with CD may have fissures, ulcerated hemorrhoids, strictures, or cutaneous abscesses around the anus. Extraintestinal manifestations include inflammatory conditions of the skin, eyes, joints, spine (ankylosing spondylitis), and liver (primary sclerosing cholangitis).[34] In children, growth and sexual development may be affected. Onset of symptoms usually occurs before the age of 30 years,[28] although the diagnosis can be difficult to make in the early stages.

Patients often come to the ED with a known diagnosis of IBD and worsening abdominal symptoms. A common reason for relapse is interruption of the medications that have kept the disease in remission. Many patients become complacent during quiescent periods and stop taking such medications. IBD requires continuous, lifelong maintenance therapy. Adherence to therapy has been shown to reduce the risk of acute attacks and cancer.[28] Common complications of IBD include formation of fistulae, strictures, and abscesses; less common but life-threatening complications include fulminant colitis, toxic megacolon, and intestinal perforation.

Toxic Megacolon

Toxic megacolon is a pathologic dilation of the colon resulting from inflammation of the smooth muscle layers of the intestine. Muscle inflammation leads to paralysis, dilation, and eventually perforation if left untreated. The hallmark of toxic megacolon is colonic dilation in a patient with a known inflammatory condition of the colon who appears systemically toxic. Presence of inflammation and toxicity differentiates toxic megacolon from other disorders that cause colon dilation, including mechanical obstruction, pseudo-obstruction, and congenital or acquired megacolon.

Toxic megacolon is typically associated with IBD or infectious colitis. The triggering event may be recent ingestion of anticholinergics, antimotility agents, narcotics, or antidepressants. Patients usually have experienced symptoms of colitis, often severe, for several days before the onset of toxic megacolon. Abdominal pain, fever, tachycardia, and abdominal distention are present. Plain radiographs are diagnostic and show a colon with a diameter of 6 cm or greater, although this feature may not be present in early stages. Treatment includes aggressive fluid hydration, intravenous corticosteroids, antibiotics covering bowel flora (see Box 95-5), and an evaluation for potential intestinal infections, especially in immunocompromised patients. Hypokalemia or hypomagnesemia should be aggressively corrected if present, as it can exacerbate colonic dilation.[34] The mortality rate has decreased over the past four decades to less than 2% as a result of early recognition and aggressive treatment.

Diagnostic Strategies

No specific laboratory tests to diagnose IBD are available, although recent tests targeting antibodies to *Saccharomyces cerevisiae* or antineutrophil cytoplasm help to differentiate between CD and UC.[30] Laboratory abnormalities may occur for a variety of reasons. Electrolyte abnormalities may be secondary to significant diarrhea, or anemia may occur from bloody stools. The erythrocyte sedimentation rate can be elevated and useful for categorizing the severity of the disease. Stools contain fecal leukocytes, but findings on stool cultures and ova and parasite examinations should be normal.

Plain radiography is not helpful in the diagnosis of uncomplicated disease but may show bowel obstruction, toxic megacolon, or free air from a perforation (Fig. 95-5). The use of plain radiographs should be limited to patients suspected of having these complications. Contrast studies can reveal lesions suggestive of IBD, including ulcerations of the mucosal surface, fistulae, and strictures. In Europe, where ultrasound technicians are more experienced in its application, ultrasonography is used to identify active disease and to look for complications.[31] Ultrasound imaging is used much less commonly in the United States. Magnetic resonance imaging can locate affected bowel segments and identify fistulae, stenoses, and abscesses and has the advantage of no radiation, which is a consideration in individuals likely to get multiple imaging studies over time. CT is the best study routinely available to evaluate extraluminal complications. CT colonography ("virtual colonoscopy"), although good for identifying cancerous lesions of the colon, does not show the typical lesions of IBD.[31] Recently,

www.ketabpezeshki.com 66485457-66963820

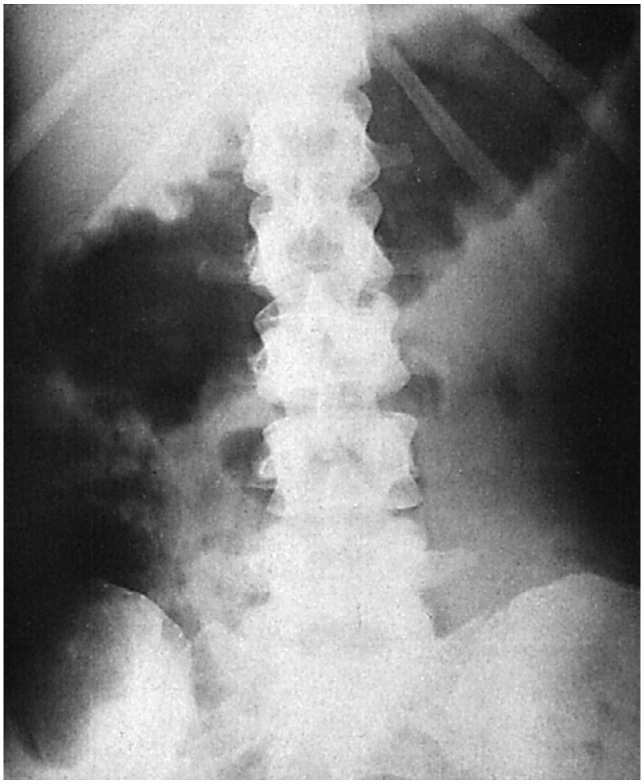

Figure 95-5. Toxic megacolon secondary to ulcerative colitis. The smooth indentations seen along the margin of the colon represent pseudopolyps.

video capsule endoscopy (VCE) has shown promise in finding small bowel pathology missed by other studies. VCE has the drawback that capsules may get stuck at stricture sites and need to be surgically removed.[35] Endoscopic evaluation with biopsy is usually required to confirm the diagnosis.[30]

Differential Considerations

Symptoms and signs are protean and overlap with those of many common abdominal conditions, including appendicitis, infectious colitis, ischemic colitis, radiation colitis, diverticular disease, cancer, and bowel obstruction. Intestinal infections commonly mimic the symptoms of IBD, and in new patients microbiologic studies for bacterial infection, including *Escherichia coli* O157 : H7, *Clostridium difficile,* and amoeba should be considered. Established patients who have recently been hospitalized or on antibiotics should be tested for *C. difficile.* Several assays may be required owing to the high false-negative rate for testing.[34]

Management

Medical management is the mainstay of therapy for most patients with IBD. In general, patients are maintained on 5-aminosalicylic acid (5-ASA) agents while asymptomatic and placed on steroids if symptoms recur. Once remission is achieved, steroids are discontinued and the patient is once more maintained on 5-ASA agents. If remission is not achieved with steroids, other agents such as antimetabolites and immunosuppressants are used (Box 95-6). The choice of agents depends on classification of the disease as mild, moderate, or severe (Box 95-7). Surgery is reserved for patients with severe disease who do not respond to medical therapy or for complications such as obstruction or fistula formation. This classic stepwise approach has recently been challenged by evidence that early initiation of immunosuppressants or antibody therapy leads to a more sustained remission and less need for surgical intervention, although this is still controversial.[36]

5-ASA agents are the first line of therapy for disease that is not severe. These agents can be administered orally, or rectally if the disease is in or near the rectum. Sulfasalazine, one of the original drugs in this category, is limited by sulfa toxicity at higher doses

Box 95-6 Medications Used in the Treatment of Inflammatory Bowel Disease

5-Aminosalicylic Acid Agents
Sulfasalazine
Mesalamine

Antibiotics
Metronidazole
Ciprofloxacin
Rifaximin

Anti–Tumor Necrosis Factor Antibody
Infliximab

Box 95-7 Disease Severity Criteria in Inflammatory Bowel Disease

Ulcerative Colitis

Mild Disease
- Fewer than four stools per day
- Stools may contain some blood
- No systemic signs of toxicity (fever, tachycardia, anemia, elevated erythrocyte sedimentation rate)

Moderate Disease
- More than four stools per day
- Minimal signs of toxicity

Severe Disease
- More than six bloody stools per day
- Signs of systemic toxicity

Crohn's Disease

Mild to Moderate Disease
- Patient ambulatory and able to eat
- No dehydration
- No toxicity
- No significant abdominal pain or mass
- Weight loss of 10%

Moderate to Severe Disease (Any of the Following)
- Mild disease that has failed to respond to treatment
- Patient may have some systemic toxicity, significant weight loss, anemia
- Fever, some abdominal pain or tenderness, intermittent nausea or vomiting

Severe Disease
- Persistence of symptoms during corticosteroid or biologic (e.g., infliximab) therapy
- High fever, persistent vomiting
- Intestinal obstruction
- Rebound tenderness
- Cachexia
- Abscess

www.ketabpezeshki.com 66485457-66963820

and has serious side effects including nausea, vomiting, anorexia, headache, and rarer conditions such as bone marrow suppression, pancreatitis, hepatotoxicity, anemia, and interstitial nephritis. A newer 5-ASA derivative, mesalamine, has less toxicity, allowing higher dosages. When IBD goes into remission after an acute flare, the patient may be continued on 5-ASA derivatives for maintenance therapy.

Antibiotics may be used for the primary treatment of IBD as well, but their use is controversial. Evidence supporting antibiotic use is stronger in CD than in UC. Metronidazole and ciprofloxacin are the most common antibiotics used, with some evidence suggesting that tobramycin or rifaximin may be beneficial as well.[37]

Oral corticosteroids are used in patients with moderate to severe disease or patients whose IBD is unresponsive to a 5-ASA agent. Steroids should be tapered when remission is achieved to avoid typical steroid side effects. Intravenous corticosteroids are reserved for hospitalized patients with severe disease. Budesonide, a newer oral corticosteroid, is degraded on its first pass through the bloodstream and has fewer systemic side effects. Prolonged use of steroids can lead to gastrointestinal mucosal injury, problems with wound healing, osteopenia with fractures, and frank osteonecrosis that may be evident only on MRI.[34]

The immunomodulating drugs azathioprine and 6-mercaptopurine are used in patients resistant to other therapies or to wean steroid-dependent patients. Patients on these medications should be assessed for bone marrow suppression and pancreatitis.[38]

The immunosuppressant agent cyclosporine is used in severe cases, often when patients are not surgical candidates. Although most patients tolerate it well, cyclosporine has significant potential toxicity, including myelosuppression, electrolyte disturbances, and hepatic and nephrotoxicity.[28] Opportunistic infections including *Pneumocystis* pneumonia have been known to occur.[32]

Infliximab, an antibody to human tumor necrosis factor alpha, is useful in advanced cases of IBD. It generally has a benign side effect profile but carries an increased risk of opportunistic infections, including tuberculosis and fungal infections.[29] Of patients receiving infliximab, 1 to 2% will experience serum sickness–like symptoms including arthralgias, myalgias, fevers, and rash.[34] Surgery is reserved for patients with severe disease refractory to medical management and for patients with complications such as intestinal obstruction, significant bleeding, abscess, or fistula. A colectomy is curative for UC and improves quality of life, but there is no curative surgery for CD. Extraintestinal manifestations usually respond to therapy for intestinal disease.[30,39]

Disposition

Consultation with a gastroenterologist is recommended before patient disposition. Most patients with an uncomplicated mild-to-moderate exacerbation of IBD need only restart their maintenance therapy if it was interrupted, or add oral corticosteroids to their regimen. Patients with severe disease or those in whom oral corticosteroids have failed to effect improvement need hospitalization for administration of parenteral corticosteroids.[30] Bowel rest does not seem to be beneficial except as preparation for surgical intervention.[40] Emergent surgical consultation should be sought for life-threatening hemorrhage, evidence of perforation, or toxic megacolon. Urgent (not emergent) surgical intervention is indicated if the bowel is obstructed. Abscesses may be treated percutaneously with imaging guidance or surgically. Chronic fistulae initially are treated medically.[38] After hospital discharge, close follow-up by the physician monitoring the patient's disease is indicated to ensure that remission is achieved in a timely fashion and that the patient complies with the suppressive therapy after the acute event. For patients in remission, endoscopic monitoring for cancer is required on an ongoing basis, although the optimal frequency of examination has not yet been defined.[38] The estimated prevalence of cancer among patients with CD is significant at 2%, and patients with UC have a 15 times greater risk for the development of colorectal cancer than the general population.[32] Up to 25% of patients with UC will eventually require colectomy for uncontrolled disease.[36]

COLONIC ISCHEMIA

Perspective

Colonic ischemia is the most common of the intestinal ischemic disorders and yet remains poorly understood.[41] Estimates place the incidence of colonic ischemia at 1 of every 2000 hospitalizations. Its presentation overlaps with that of many other significant abdominal diseases, and the disorder is difficult to diagnose without endoscopic visualization of the colonic mucosa. Although elders are most at risk, with 90% of cases occurring in those older than 60 years, the condition can occur in all age groups.[42] Both sexes are equally affected. In one study more than 50% of persons admitted with colonic ischemia were initially diagnosed with IBD. Because there is no specific treatment, outcomes usually are good and recurrences are rare; difficulty in making the diagnosis does not result in significant morbidity.

Principles of Disease

The exact cause of colonic ischemia is unknown. Isolated ischemia without small bowel involvement usually is a result of nonocclusive microvascular disease of the colon and not large vessel (mesenteric artery) occlusion. The primary insult is a low–blood-flow state associated with a variety of factors, including congestive heart failure, vasoactive drugs, atherosclerosis, renal failure, and recent cardiac or vascular surgery.[42-44] Factors that have recently been implicated are infections, especially *E. coli* O157 : H7, and thrombophilia.[41] Younger patients may develop colonic ischemia in the setting of collagen vascular disease, hematologic disorders, long-distance running, or cocaine abuse. Medications associated with colonic ischemia through a variety of mechanisms include digoxin, pseudoephedrine, and sumatriptan, among others. The colonic vascular system generally enjoys significant collateral flow, but in some patients this protective mechanism is tenuous, predisposing the affected person to ischemia from low-flow events.[42] In addition, colonic arterioles seem to be particularly sensitive to vasoconstrictive influences, and the rapidly growing intestinal mucosa is especially vulnerable to interruptions in blood flow. High intraluminal pressures that normally develop within the colon can also alter intestinal perfusion significantly. Colonic ischemia can occur in any part of the colon, including the rectum, but for unknown reasons it occurs most often in the left colonic segment.

Colonic ischemia represents a spectrum of disease whose manifestations vary with the extent of the ischemic insult. In most cases the ischemic episode is self-limited, and the condition resolves completely with conservative therapy, but in one third of patients a prolonged or severe insult results in scarring or stricturing of the colon and chronic symptoms.[42] If the ischemia is transmural, gangrene and intestinal perforation are possibilities. Chronic mild inflammation results in intermittent symptoms similar to those of IBD.

Clinical Features

The presentation of colonic ischemia typically involves the acute onset of mild crampy abdominal pain in the left lower quadrant with abdominal distention and almost always blood in the stool.[45] The typical patient has had recent surgery or has a significant medical illness. Some patients do not have pain. Nausea and

www.ketabpezeshki.com 66485457-66963820

vomiting can occur with obstruction secondary to a stricture or an ileus. Tenderness over the affected colon may be present but often is not dramatic. Peritoneal findings, fever, and a significantly elevated WBC count suggest gangrenous bowel and perforation. Toxic megacolon is a recognized complication.

Diagnostic Strategies

No sensitive or specific biochemical markers for colonic ischemia are recognized, although biochemical abnormalities such as elevated serum lactate, phosphate, and alkaline phosphate levels may be present. These abnormalities may be absent in milder disease and are often not observed in more significant disease until after irreversible damage has occurred. A complete blood count to exclude significant anemia and to look for a leukocytosis suggestive of perforation is appropriate. Serum electrolytes should be checked if diarrhea or vomiting has been significant or prolonged. Blood and WBCs in the stool are common findings in several of the entities that present similarly to colonic ischemia, including IBD and infectious colitis. A positive occult stool guaiac test result should ensure that the patient is eventually evaluated for colonic carcinoma. Unfortunately, the definitive diagnosis of colonic ischemia rarely is made in the ED.[42]

Plain Radiography

Plain radiographs often show only nonspecific dilated bowel. Findings specific for colonic ischemia occur in only 20% of patients. The classic findings are intraluminal prominences, known as *thumbprinting*, representing submucosal hemorrhage and swelling. Thumbprinting can also be seen with other disorders, including IBD, colonic infections, and hemorrhage secondary to anticoagulants. Other findings consistent with colonic ischemia include wall thickening and ahaustral segments. Air in the portal venous system or bowel wall suggests imminent intestinal infarction.

Barium Enema

Thumbprinting is detected more often by barium enema than by plain radiography, but barium enemas have largely been replaced by colonoscopy.

Colonoscopy

Colonoscopy with colonic biopsy is the preferred method to diagnose colonic ischemia because it visualizes the abnormal colonic mucosa better than barium enema and affords the opportunity to take biopsy specimens to differentiate between cancer and other nonischemic causes of colitis. Colonoscopy can also detect necrotic bowel by its distinct cyanotic or black appearance. If colonoscopy is delayed, pathologic changes consistent with colonic ischemia may have already improved or resolved. The diagnosis may be missed on colonoscopy in up to one third of cases.[43]

Computed Tomography

Although CT does not allow the definitive diagnosis of colonic ischemia, it can exclude other disorders. CT features suggestive of colonic ischemia include thumbprinting, wall thickening, and luminal narrowing and inner wall hypoperfusion ("double halo sign").[42]

Angiography

Angiography is usually not helpful in either the diagnosis or the management of colonic ischemia. In most cases the blood flow defect is at the microvascular level and has resolved by the time the patient seeks evaluation.[46] The exception is the case in which only the ascending colon is affected, suggesting a superior mesenteric artery thrombosis.

Differential Considerations

The symptoms of colonic ischemia are nonspecific and overlap with those of numerous other disorders including IBD, radiation proctocolitis, infectious colitis, and other causes of nonprofuse lower gastrointestinal bleeding. If strictures are present, the possibility of diverticulitis or colon cancer should be considered.

Management

In the absence of surgical complications, the treatment of colonic ischemia is supportive and includes hospitalization for bowel rest, hydration, and pain management, with some authors recommending antibiotic coverage.[42] NSAIDs are best avoided, as are oral cathartics or bowel preparation regimens that may lead to perforation. Broad-spectrum antibiotics covering bowel flora are indicated for patients with more significant symptoms (see Box 95-5). If colonic ischemia is precipitated by an episode of hypotension, the underlying cause of the hypotension must be sought and treated aggressively, and cardiac output should be maximized.[42] Vasopressors should be avoided to prevent worsening of ischemia; steroids should also be avoided because they may facilitate bowel perforation. Colonic distention, if present, can be relieved acutely through the use of a rectal tube; surgical consultation is recommended in these cases. Decompression of the colon may result in a lowering of transmural pressure and improved colonic perfusion. Sepsis, peritoneal changes, free abdominal air, significant fever, massive bleeding, and a significant leukocytosis suggest bowel necrosis or perforation and should prompt emergent surgical consultation.[42,44]

Disposition

Patients with mild symptoms and no significant abdominal tenderness or bleeding can be managed on an outpatient basis and referred for colonoscopy. Stool studies including cultures for bacteria, microscopy to look for ova and parasites, and a *C. difficile* titer are helpful if the diagnosis is uncertain. Patients with more significant findings, especially if the diagnosis of gangrenous bowel cannot be excluded, require hospitalization. A high mortality rate (60%) is expected for patients undergoing emergent surgery, although deaths before the age of 50 years are rare.[44] Most patients improve without surgical intervention, and only 5% have a recurrence of colonic ischemia. In those with continuing significant symptoms, colectomy is usually curative.

RADIATION PROCTOCOLITIS

Perspective

Radiation proctocolitis is a common side effect of radiation therapy, occurring in 50 to 75% of patients receiving radiation to the pelvis. The disease has two distinct presentations: acute and chronic. Acute radiation proctocolitis begins during or shortly after a course of radiation therapy, is usually easily diagnosed, and is self-limited. Chronic radiation proctocolitis occurs in 5 to 10% of patients who have undergone pelvic radiation therapy and typically begins any time up to 2 years after the end of radiation therapy, although onset of clinical manifestations may be delayed beyond 2 years.[48] Some cases have occurred decades later. Patients with more severe acute radiation proctocolitis seem to be prone to chronic proctocolitis.[49] Because of its nonspecific presentation

www.ketabpezeshki.com 66485457-66963820

and delayed appearance, the diagnosis of chronic radiation proctocolitis can be challenging. Unfortunately there is a paucity of robust research evaluating the best approach to management of this disorder.[50]

Principles of Disease

Radiation causes tissue injury through the creation of oxygen free radicals, which damage cellular DNA. The faster the growth rate of cells, the more DNA damage affects their function. For this reason, radiation is an effective treatment for neoplastic disease, but it also damages rapidly growing normal tissue, such as intestinal epithelium. Radiation damage also may adversely affect anal sphincter function, leading to bowel incontinence.

Acute Radiation Proctocolitis

Intestinal epithelium normally is sloughed and replaced at a rapid rate. After the start of radiation therapy, growth of replacement epithelium is slowed, but sloughing continues at the preexposure rate. This mismatch leads to gaps in the epithelium, which over time coalesce into ulcerations. In addition, edema and inflammatory changes of the submucosa cause excessive mucus secretion and bleeding. When radiation therapy has ended, the cycle of damage stops, and healing occurs over the next few weeks.

Chronic Radiation Proctocolitis

The pathologic mechanism in chronic radiation proctocolitis is entirely different from that in acute radiation proctocolitis. Chronic radiation proctocolitis results from a progressive endarteritis with abnormal tissue collagen deposition. Affected intestine has a decreased microvascular density, with subsequent decreased perfusion.[51] Over time, affected bowel gradually becomes more ischemic, leading to ulceration, scarring, and narrowing of the bowel lumen. Frank necrosis and perforation, although uncommon, can occur. Long-term outcomes in chronic radiation proctocolitis have not been well studied, but it seems that patients in whom fistulae and persistent bleeding strictures develop have the poorest prognosis.[49]

Clinical Features

Acute radiation proctocolitis manifests with abdominal pain, bleeding, and tenesmus. Onset during the course of radiation therapy, typically after several treatments, suggests the diagnosis. Fecal urgency and incontinence can be devastating to quality of life.[51]

Chronic radiation proctocolitis has a more insidious onset with a variety of presentations, including ulcerative disease, stricture with or without obstruction, fistulae, and bowel perforation. Symptoms may be similar to those in acute disease, with tenesmus, diarrhea, and urgency. Bleeding is common but usually is not hemodynamically significant. Decreased caliber of stool with increased straining or constipation suggests a stricture. Fistulae can develop between affected bowel and any adjacent organ, but the most common fistulae are rectovaginal. Some patients may exhibit anal sphincter dysfunction and loss of bowel control. Symptoms tend to have a significant negative impact on the quality of life.[49]

Diagnostic Strategies

The diagnosis of acute radiation proctocolitis is made clinically on the basis of the development of typical symptoms in the setting of radiation therapy. Further evaluation is usually not warranted.

Chronic radiation proctocolitis typically is a diagnosis of exclusion. Endoscopy can be suggestive, revealing pale, thickened, and friable mucosa with prominent telangiectasias. Biopsy specimens often show only nonspecific chronic inflammation. In some cases, endoscopy may be technically difficult because of scarring and reduced mobility of the intestine. Barium enema is an acceptable alternative when endoscopy is problematic, as long as bowel perforation is not a concern.

Differential Considerations

In chronic radiation proctocolitis, the possibility that symptoms are a result of recurrence of the initial malignancy or a new malignancy induced by radiation exposure must be entertained. Symptoms of chronic radiation proctocolitis generally are clinically indistinguishable from those of other causes of bowel inflammation, including IBD, infectious colitis, and ischemic colitis.[52]

Management

Treatment of acute radiation proctocolitis is symptomatic, and a therapeutic plan should be developed in conjunction with the patient's radiation therapist. Steroid enemas to reduce inflammation and water-absorbing stool softeners to reduce mucus-containing diarrhea are helpful. Reduction of the daily radiation dose also can reduce symptoms significantly.

Chronic radiation proctocolitis treatment also is symptomatic. If rectal involvement is significant, stool softeners, analgesics, anti-inflammatory agents (e.g., sulfasalazine, balsalazide), and sucralfate enemas are helpful. Metronidazole is beneficial when added to anti-inflammatory therapy. Continued rectal bleeding can be controlled with topical formalin or laser photocoagulation.[50] Minimally symptomatic strictures can be managed initially with stool softeners and enemas as needed. Some strictures have a reversible edema component, so the extent of narrowing may lessen after treatment. Fistulae and significant strictures generally require surgical repair. Approximately 20% of all patients with chronic radiation injury to the intestinal tract require some type of surgical intervention. Biopsy specimens from ulcerations associated with chronic injury should be obtained to exclude malignancy.

Disposition

Suspected perforation mandates emergent surgical consultation, and signs of bowel obstruction should prompt urgent surgical consultation. Unless symptoms are severe, patients with acute or chronic radiation proctocolitis can usually be managed on an outpatient basis under the care of their radiation therapist or gastroenterologist. With acute disease, symptoms typically resolve several weeks after radiation treatments have been completed. Mild chronic disease typically resolves with medical therapy, but more severe symptoms often require aggressive intervention.

KEY CONCEPTS

- New or atypical symptoms in a patient with known IBS should prompt an evaluation for other abdominal pathology.
- A new diagnosis of IBS should be left to the primary care setting; the purpose of the ED evaluation is to exclude other abdominal disorders.
- A positive result on testing for fecal occult blood should never be assumed to be caused by diverticula. An appropriate investigation to exclude malignancy is essential.
- Uncomplicated diverticulitis can be diagnosed and treated without imaging in many patients.

www.ketabpezeshki.com 66485457-66963820

- An LBO should prompt an evaluation for malignancy.
- Gangrene or perforation should be suspected in any patient with persistent unexplained tachycardia, fever, or remarkable abdominal tenderness that is associated with intestinal disease.
- Volvulus often appears as a nonspecific large bowel obstruction on plain radiographs.
- Although typically a disease of older persons, volvulus can occur at any age.
- Intussusception in adults most commonly is associated with a significant cause, often a malignancy.
- Intussusception in adults usually manifests as a partial small bowel obstruction and rarely is associated with the classic triad of abdominal pain, mass, and heme-positive stool that is seen in children.
- IBD is a lifelong relapsing disorder that can be treated with a variety of therapies. Management decisions are best made in consultation with the physician who will be providing ongoing care for the patient.
- Treatment of uncomplicated IBD depends on the clinical classification of disease severity (see Box 95-7).
- A new diagnosis of IBD in an elderly patient should be made only after the exclusion of colonic ischemia.
- Chronic radiation proctocolitis should be considered in any patient with a history of irradiation of the pelvis or abdomen who has symptoms of gastrointestinal inflammation. This is true regardless of how long ago the radiation therapy was received.

CHAPTER 96

DISORDERS OF THE ANORECTUM

Wendy C. Coates

PERSPECTIVE

Patients visit the emergency department (ED) with a variety of anorectal complaints. Such problems may be self-limited or may signify the presence of an underlying medical condition. A high degree of sensitivity and a professional demeanor should be maintained in interactions with these patients, who may find it difficult to discuss historical details openly and to describe physical complaints related to this area of the body and its function.

PRINCIPLES OF DISEASE

The anorectum marks the end of the alimentary canal. From its beginning at the rectosigmoid junction at the level of the third sacral vertebra (S3), the rectum follows the sacral curvature for 12 to 15 cm and then sharply turns posteriorly and inferiorly at the puborectalis muscle (Fig. 96-1). Here the anal canal begins its 4-cm course to the anal verge, the orifice whereby stool exits the body. It is supported by three muscle groups, the levator ani and the internal and external anal sphincters. Anal valves are located 2 cm proximal to the anal verge at the dentate line. Above the valves are the anal crypts, which contain mucous glands to provide lubrication during defecation. These constitute a nidus for abscess formation, if occluded. Proximal to the crypts are the columns of Morgagni, where the epithelium of the anal canal changes from pink columnar (as in the rectum) to squamous.[1]

The superior, middle, and inferior hemorrhoidal arteries provide the blood supply to the anorectum. They arise from the inferior mesenteric, internal iliac, and internal pudendal arteries, respectively. The superior hemorrhoidal veins drain into the portal system, and the inferior hemorrhoidal veins drain into the caval system. Lymphatic drainage is to the inferior mesenteric nodes above the dentate line and to the inguinal nodes from all areas of the anorectum.[1]

Sympathetic and parasympathetic nervous systems function together to retain the contents of the rectum until evacuation is desired. Continence is maintained when sympathetic fibers from L1 to L3 (upper rectum) and presacral nerves (lower rectum) inhibit contraction of rectal smooth muscle and L5 fibers cause the internal sphincter to contract. Elimination occurs when parasympathetic fibers from the anterior roots of S2 to S4 cause the rectal wall to contract and the internal sphincter to relax. Voluntary external sphincter control is mediated by motor branches of the pudendal nerve (S2, S3) and the perineal branch of S4. The levator ani is supplied by the pudendal nerve and pelvic branches of S3 to S4 fibers. Sensory perception of rectal distention involves a signal pathway from extramural receptors to parasympathetic fibers from S2 to S4. The abundant sensory nerve endings of the distal anal epithelium perceive sensations that are transmitted by the pudendal nerve.[1]

Defecation begins as the rectum becomes distended, the internal sphincter relaxes, and stool enters the anal canal. At an appropriate time and place, the external sphincter is relaxed to complete the process of elimination. Sometimes voluntary straining is needed to assist in the passage of stool. When the Valsalva maneuver is performed, the abdominal muscles contract, the rectal angle straightens, and the pelvic floor descends. To postpone defecation, the external sphincter contracts voluntarily. This contraction relaxes the rectal wall and quells the urge to defecate unless there is an underlying sphincter disorder or an overwhelming volume of stool.[1]

CLINICAL FEATURES

History

A complete history of anorectal and gastrointestinal (GI) symptoms and the presence of systemic disease elucidate the diagnosis of most anorectal disorders (Box 96-1; Fig. 96-2). Common complaints include bleeding, swelling, pain, itching, and discharge. Standard historical questions about time and circumstances of onset, duration, quality, and exposure to radiation should be asked. Alterations in bowel habits should be noted. These include changes in color, frequency, or consistency of the stool and the presence of straining, flatus, and incontinence of solid or liquid stool. Persons with underlying GI disorders (e.g., Crohn's disease, cancer, polyps) are predisposed to atypical presentations of anorectal problems. Similarly, those with underlying systemic diseases such as acquired immunodeficiency syndrome (AIDS), cancer, diabetes mellitus, and coagulopathy are prone to develop more serious complications of standard anorectal conditions. Finally, patients should be asked directly about sexual practices involving the anus.[2]

Rectal Bleeding

The color, amount, and relationship to defecation are important factors in establishing the cause of rectal bleeding. Approximately 10 to 20% of the population experiences rectal bleeding at some time.[3] Pain and bright red blood signify anal fissures or hemorrhoids. Fissure pain is sharp, sudden in onset, and not associated with swelling, whereas pain from a prolapsed or thrombosed hemorrhoid is gnawing, continuous, and of more gradual onset. Painless rectal bleeding occurs with internal hemorrhoids, cancer, or precancerous lesions.

The relationship of bleeding to defecation is important. Visible blood on the toilet paper usually is caused by anal fissures or external hemorrhoids; however, minute quantities can result from any irritating condition. Bright red blood that drips into the toilet bowl or streaks around the stool is caused by internal hemorrhoids. Blood mixed with stool originates proximal to the rectum, whereas melena indicates a very proximal source. Bloody mucus is associated with cancer, inflammatory bowel disease, and proctitis.[3]

Swelling and Masses

Patients who report a swelling near the anus or have the sensation of rectal fullness often list hemorrhoids as their chief complaint. Painful swellings that bleed usually are thrombosed hemorrhoids, but other painful lesions such as abscesses, pilonidal disease, and hidradenitis suppurativa must be considered. Painless, itchy swellings may be caused by condylomata acuminata or secondary syphilis. A mass protruding through the anal orifice may signal rectal prolapse. Perianal and rectal carcinoma should be considered in older persons and those with long-standing anorectal complaints.[2]

Pain and Itching

Severe, episodic anorectal pain that is not associated with bleeding or swelling may represent proctalgia fugax or levator ani syndrome. Perianal itching (pruritus ani) is caused by any lesion that makes hygiene difficult to maintain or may be attributed to certain foods or medications.

Physical Examination

The physical examination should take place in private, with the patient's modesty respected. The patient can then relax the external sphincter to facilitate a complete examination. The patient is placed in the left lateral decubitus position and covered with a sheet. The buttocks are inspected for dermatologic manifestations of disease and then gently spread apart to expose the anal orifice. Elements of personal hygiene are noted, in addition to anatomic disruptions such as fissures, skin tags, lesions, protruding hemorrhoids, or abscesses. The patient is asked to strain; the integrity of the pelvic floor is assessed, and prolapse of hemorrhoids or rectal mucosa is noted. Next, a well-lubricated gloved finger is placed flat against the anal opening, exerting gentle pressure until the external sphincter relaxes and allows the finger to enter the anus. Anal sphincter tone can be assessed by asking the patient to squeeze the anal muscles against the examining finger. By sweeping the finger in a circumferential manner, accessible areas of the anorectum can be examined for masses and areas of tenderness. The cervix or prostate is palpated through the rectal wall. A bidigital examination reveals masses and tender areas at the distal portion of the anal canal and perineum. On withdrawal, the contents on the glove can be assessed for frank or occult blood, mucus, or pus.

Direct visualization can be accomplished by anoscopy. With the patient positioned as described, the lubricated anoscope is inserted into the anus with the obturator in place. The obturator is removed to allow a circumferential view of the rectal mucosa. Attention is directed to sites of bleeding, hemorrhoids, masses, or abnormal tissue and finally the dentate line and anal epithelium.

SPECIFIC ANORECTAL PROBLEMS

Hemorrhoids

Perspective

When the Philistines defeated the Israelites, the book of I Samuel reports the fate of the avengers: "A deadly panic had seized the whole city, since the hand of God had been very heavy upon it. Those who escaped death were afflicted with hemorrhoids, and the outcry from the city went up to the heavens."[4] In 1815 the

www.ketabpezeshki.com 66485457-66963820

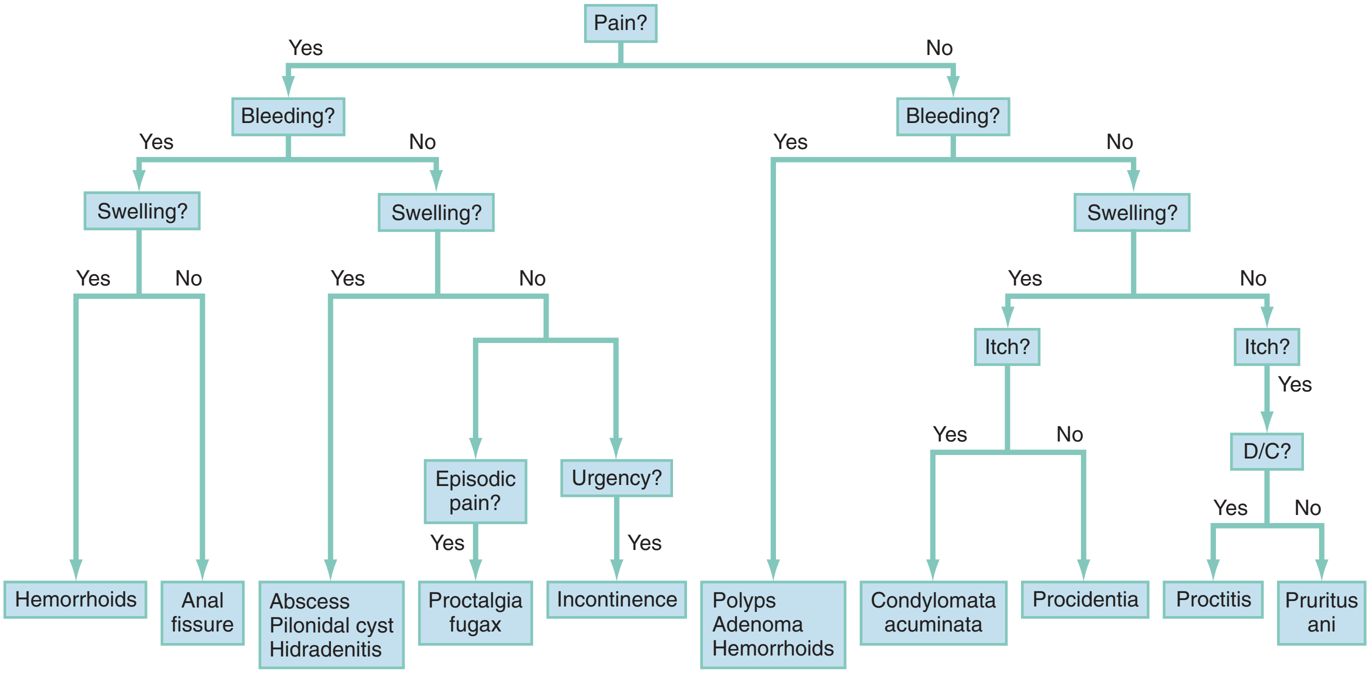

Figure 96-2. Algorithm for anorectal complaints. *D/C,* discharge.

battle of Waterloo marked the defeat of Napoleon's army. Speculation purports that the great leader suffered from hemorrhoids at the time of his defeat.[5] Hemorrhoidal disease continues to afflict modern humans, with a 5% incidence in the U.S. population. Both sexes are affected, and an increased frequency has been documented among whites, rural dwellers, and those of high socioeconomic status.[6]

Principles of Disease

Hemorrhoids occur when the anal vascular cushions become engorged. Rather than forming a continuous ring around the anal canal, the submucosa forms three distinct cushions of tissue that are richly supplied with small blood vessels and muscle fibers. Blood supply to these cushions is from the superior rectal artery, with some contribution from the middle and inferior hemorrhoidal arteries, which explains why hemorrhoidal bleeding is bright red. The muscularis submucosa cushions the anal canal during defecation to prevent injury and to aid in fecal continence.[7]

As the supportive tissue deteriorates, often starting in the third decade of life, venous distention, prolapse, bleeding, and thrombosis may occur. Some controversy exists about whether straining and constipation cause these changes by producing venous backflow when intra-abdominal pressure increases.[7,8] In pregnant women, direct pressure on a hemorrhoidal vein can produce symptomatic hemorrhoids. Up to one third of pregnant women experience hemorrhoids in the last trimester of pregnancy or the postpartum period. An increased incidence of thrombosed hemorrhoids is associated with traumatic deliveries.[9,10] Some familial predisposition is recognized, but whether this is a result of genetics or acquired factors such as diet is unknown.

Hemorrhoids are not varicose veins; they are normal structures that manifest symptoms when the muscularis submucosa weakens and the anal cushions are displaced distally.[7] Conditions that increase sphincter tone correlate with a higher prevalence of hemorrhoids.[8] Portal hypertension does not cause hemorrhoids in adults. The incidence of symptomatic hemorrhoids is similar in patients with and in those without portal hypertension. Rectal bleeding in patients with portal hypertension may be caused by rectal varices, which are vascular communications between the superior and middle hemorrhoidal veins.[6,11] A major exception to this observation occurs in the pediatric population; children with portal hypertension are susceptible to hemorrhoidal exacerbations.[12,13]

Clinical Features

A careful history is needed to confirm the presence of hemorrhoids because many patients use this term to refer to any perianal condition. Bleeding with defecation is the most common complaint, and unless the hemorrhoids are thrombosed, it usually is painless. Patients report variable amounts of bright red blood on the toilet paper or in the toilet bowl. Many complain of swelling, itching, mucoid discharge, or simply the presence of a moist perianal area. Further history should address recent stool patterns, such as diarrhea or constipation; chronic medical problems, such as portal hypertension or bleeding disorders; and a dietary and family history.

Frequent bowel movements, prolonged sitting, heavy lifting, and straining while defecating exacerbate hemorrhoidal symptoms. Although straining is cited as a cause of hemorrhoids, it also may be a result of them when the patient is constipated from delaying defecation because of fear of pain. Physical examination should ascertain the type and degree of hemorrhoids. This can be accomplished by a visual inspection at rest and during straining. Nonprolapsing hemorrhoids can be visualized on anoscopy as a focus of bleeding or as they bulge when the patient is asked to strain while the anoscope is removed. Anoscopy is painful and not useful in cases of prolapsed or thrombosed hemorrhoids.

Hemorrhoids are classified according to their location and severity (Table 96-1). *External* hemorrhoids originate *below* the dentate line and receive their blood supply from the inferior hemorrhoidal plexus. They are covered with modified squamous epithelium (anoderm) and resemble the surrounding skin. Two syndromes are common. First, the veins beneath the skin of the hemorrhoid become dilated and the surrounding subcutaneous tissue becomes engorged, causing swelling or pressure after

www.ketabpezeshki.com 66485457-66963820

defecation. Painless, bright red bleeding may occur. Second, the veins can become thrombosed as clots form within them (Fig. 96-3A). This produces acute pain and tenderness to palpation. A bluish discoloration often is noted.

Internal hemorrhoids originate *above* the dentate line and receive their blood supply from the superior hemorrhoidal plexus (Fig. 96-3B). They are covered with a mucosal surface consisting of transitional or columnar epithelium that looks very different from the surrounding anoderm. They are classified according to severity (Table 96-2). Symptoms and signs range from mild, painless bleeding with defecation to irreducible prolapse with unremitting and debilitating pain. First-degree internal hemorrhoids protrude into the lumen of the anal canal, causing a feeling of fullness. Because the mucosal wall lacks sensory nerve endings, these lesions do not cause pain. Second-degree internal hemorrhoids temporarily prolapse outside the anal canal during defecation but spontaneously return to their normal position at the end of the bowel movement. Both first- and second-degree hemorrhoids are amenable to medical management. Third-degree internal hemorrhoids prolapse spontaneously or during defecation and remain outside the body until they are manually replaced into the anal canal. A throbbing, pressure-like pain may accompany bleeding and subsides when the hemorrhoids are reduced. Fourth-degree internal hemorrhoids cannot be reduced and are permanently prolapsed. Continued prolapse leads to the formation of a thrombus with possible progression to gangrene. Definitive treatment for the intense pain and thrombosis is surgical.[8,14]

Management

The symptoms of nonthrombosed external and nonprolapsing internal hemorrhoids can be ameliorated by the standard regimen—warm water, analgesics, stool softeners, and high-fiber diet (WASH)—aimed at combating the problems that led to the hemorrhoids' formation (Box 96-2). Anal canal pressures decrease in warm water (40° C). Patients can direct a shower stream at the area for several minutes or take sitz baths. Mild oral analgesic agents reduce the pain. Several over-the-counter preparations are available for the treatment of hemorrhoidal symptoms; however, their use is directed at improved hygiene and temporary symptom relief rather than correction of the condition.[15] The use of topical anesthetics, corticosteroids, astringents (e.g., witch hazel), mineral oils, and cocoa butter is controversial. Prolonged use of topical corticosteroids produces atrophic skin changes and is discouraged.[7] Stool softeners can make the passage of stool easier, to prevent straining. A high-fiber diet (consumption of 20 to 30 g of dietary fiber per day) produces stool that is passed more easily.[16]

Patients with second- or third-degree internal hemorrhoids also benefit from this regimen; however, permanent resolution of their symptoms may require surgical intervention (Table 96-3). These patients can be discharged from the ED with the WASH regimen and referred to a surgeon for banding, sclerotherapy, or elective

CLASSIFICATION	MANAGEMENT
Thrombosed external hemorrhoids	Excision in emergency department
Second- and third-degree internal hemorrhoids	Elective surgical repair Banding Sclerotherapy Hemorrhoidectomy
Fourth-degree hemorrhoids (nonthrombosed)	Nonemergent hemorrhoidectomy
Thrombosed or gangrenous fourth-degree internal hemorrhoids	Emergent hemorrhoidectomy

hemorrhoidectomy. Patients with acute, gangrenous, thrombosed fourth-degree internal hemorrhoids should be referred for emergent hemorrhoidectomy.

Acutely thrombosed external hemorrhoids can be excised (not incised and drained) in the ED to provide prompt relief within the first 48 hours after the onset of symptoms (Fig. 96-4). Incision results in incomplete evacuation of the clot, subsequent rebleeding, swelling, and the formation of a skin tag.[8,17] If not excised, the thrombosed external hemorrhoid resolves spontaneously after several days when it ulcerates and leaks the dark accumulated blood, with relief of associated symptoms. Residual skin tags may persist, making anal hygiene more challenging. In the ED setting, this procedure is not commonly performed in pediatric patients, pregnant women, or immunocompromised patients.

Nonsurgical therapy with topical nifedipine (0.3%) and lidocaine (1.5%) gel has been shown to alleviate symptoms when applied twice daily for 2 weeks. The purported effectiveness of this regimen for treatment of thrombosed hemorrhoids is related to the ability of nifedipine to modulate resting sphincter tone and thereby reduce the associated pain and inflammation. However, this regimen is not widely used.[18]

Figure 96-5. Lateral anal fissure. (Courtesy Gershon Effron, MD, Sinai Hospital of Baltimore. From Seidel HM, et al: Mosby's Guide to Physical Examination, 4th ed. St Louis, Mosby, 1999.)

Anal Fissures

Principles of Disease

The development of an anal fissure is the most common cause of intensely painful rectal bleeding of sudden onset. A superficial tear in the anoderm results when a hard piece of feces is forced through the anus, usually in patients who are constipated. Although anyone can experience an anal fissure, it is most common in the 30- to 50-year age bracket.[19] It is the most commonly encountered anorectal problem in pediatric patients, especially infants.[20,21] Males and females are affected equally. Most fissures occur along the posterior midline, where the skeletal muscle fibers that encircle the anus are weakest. Anterior midline fissures are more common in women than in men. Fissures that occur elsewhere are more likely to be associated with systemic disease such as leukemia, Crohn's disease, human immunodeficiency virus (HIV) infection, tuberculosis (TB), or syphilis.[19] Fissures not treated promptly may become chronic, with development of a classical "fissure triad" of deep ulcer, sentinel pile, and enlarged anal papillae (Fig. 96-5). A sentinel pile forms when the skin at the base of the fissure becomes edematous and hypertrophic. A resolving sentinel pile can form a permanent skin tag and may be associated with a fistulous tract.

Clinical Features

The patient reports sudden, searing pain during defecation that may be accompanied by a small amount of bright red blood in the stool or on the toilet paper. This is followed by a nagging, burning sensation that lasts for a few hours from internal sphincter spasm. Subsequent bowel movements are excruciating, and the external sphincter can exhibit a reflex spasm. Physical examination must be performed cautiously to avoid further spasm and pain. The depth of the fissure, its orientation to the midline, and the presence of a coexisting sentinel pile or edema are noted. Rectal examination during an acute exacerbation often is impossible because of pain and sphincter spasm.[19]

Management

Specific measures for the treatment of anal fissures are summarized in Box 96-3. Treatment with the WASH regimen (see Box

www.ketabpezeshki.com 66485457-66963820

96-2) focuses on eliminating constipation with a bulking agent, stool softener, and high-fiber diet. Warm sitz baths and limited use of topical anesthetics may be helpful. Parental encouragement of pediatric patients helps prevent encopresis, which can result from a fear of painful bowel movements. Most acute, uncomplicated fissures resolve in 2 to 4 weeks. For adult patients with chronic anal fissures, application of various topical agents aimed at reducing sphincter pressures has been effective.[22-24] Hyperbaric oxygen has been used successfully for adjunctive therapy.[25]

Lidocaine ointment is effective in treating chronic anal fissures. In addition, nitroglycerin ointment applied topically to the anoderm two or three times daily has been shown to relieve the pain from anal fissures. Although it was not associated with more rapid healing, patients receiving this therapy have reported a higher level of comfort during the healing process. The typical side effect of a vasodilatory headache may be experienced by some patients.[26]

Nifedipine gel (0.2%) in combination with lidocaine (1.5%) applied to the anal area twice daily is effective in promoting healing and reducing discomfort in the management of anal fissures. The mechanism of healing is thought to be the reduction of anal canal pressures by local calcium channel blockade.[27,28] When the efficacy of calcium channel blockers was compared directly with that of topical nitrates, the rates of healing and recurrence were similar; however, the incidence of side effects was lower in one study.[29]

Injection of botulinum toxin by colorectal surgeons (2.5 to 5.0 units of Botox preparation) is effective in relaxing the sphincter tone by inhibiting acetylcholinesterase release but may cause temporary, reversible fecal incontinence.[24,27,30-33] Injection into the external (rather than internal) sphincter muscles may reduce this undesirable side effect. It has not yet been studied as a primary treatment in the ED or primary care setting. In comparison with the topical treatments, botulinum toxin may provide some advantages in its rate of permanent healing[34]; however, the first line of therapy is still dietary modification and the application of topical agents because of their cost, ease of application, and benign side effect profiles.[24,33] Long-term treatment of recurrent fissures focuses on reducing resting anal pressures and may require anal dilation performed with the patient under anesthesia or surgical correction to reduce the tone of the internal sphincter.[19]

Abscesses and Fistulae

Principles of Disease

Anorectal abscesses and fistulae occur in otherwise healthy adults when the mucus-producing glands at the base of the anal crypts occlude. Abscesses are a manifestation of inflammatory bowel disease, trauma, cancer, radiation injury, and infection (TB, lymphogranuloma venereum, actinomycosis). Common causative bacteria are *Staphylococcus aureus, Escherichia coli, Streptococcus, Proteus,* and *Bacteroides.*[35] An increased incidence in infants (85% in male babies) has been reported to be associated with congenital abnormalities.[36]

Management

General Approach. Anorectal abscess is an acute disease that naturally progresses to fistula formation in the body's attempt to drain the infection spontaneously. Symptoms vary depending on the site of infection, but incision and drainage constitute the curative treatment in all cases (Table 96-4). Delay of medical management may allow extension of the infection and eventual compromise of the sphincter mechanism.[37] Adjunctive antimicrobial therapy is indicated in patients who are immunocompromised or diabetic or have valvular heart disease. Tetanus immunization status should be verified. The sites of anorectal abscess formation are depicted in Figure 96-6. The difficulty in diagnosis is that pain often precedes physical findings of a mass or fluctuance. Approximately 34% of patients with AIDS develop anorectal abscesses and fistulae, which may include opportunistic organisms in addition to the usual ones. HIV-infected patients appear to be more likely than their seronegative cohorts to have an incomplete fistulous tract. This condition prevents adequate spontaneous drainage, highlighting the urgency of treating these patients promptly. A small incision is desirable, when possible, because wound healing in general may be impaired.

Treatment of Specific Abscesses

Perirectal and Perianal Abscesses. Perirectal and perianal abscesses are the most common (40-45%) and produce painful swelling at the anal verge that is worsened by defecating or sitting. Most patients are afebrile. Physical examination reveals localized tenderness, erythema, swelling, and fluctuance. ED management by incision and drainage with same-day discharge is possible in patients who do not have comorbidity (e.g., diabetes mellitus, extremes of age, compromised immune status). Some patients

Table 96-4 Types of Abscesses of the Anorectum

may be unable to tolerate the procedure without general or regional anesthesia. The WASH regimen (see Box 96-2) may alleviate postprocedure discomfort. Antibiotics are unnecessary in healthy adult patients except in cases involving associated cellulitis.[38,39]

Ischiorectal Abscess. Approximately 20 to 25% of abscesses form outside the sphincter muscles in the buttocks, and patients report severe pain. The diagnosis is obvious if an indurated mass is seen on the buttocks but is more difficult if the abscess is deep. Patients often have fever and leukocytosis. If there is no induration, a needle aspirate can confirm the presence of pus. Although many of these abscesses will require drainage performed with the patient under general anesthesia, superficial abscesses can be treated in the ED as for perianal abscess. If the patient is febrile, a short course of antibiotics, such as cephalexin, may be considered, beginning with a parenteral dose before drainage, followed by 3 to 7 days of an oral agent.[39,40]

Intersphincteric Abscess. One fourth of abscesses form in the space deep to the external sphincter and inferior to the levator ani. The infection tracks cephalad and may appear to be a mass in the rectum and can be confused with a thrombosed internal hemorrhoid. Patients report continuous rectal pressure and a throbbing pain exacerbated by defecation or sitting. They may have fever and leukocytosis. External evidence of inflammation may be lacking, but rectal examination reveals an erythematous, indurated, sometimes draining mass. Associated fistulae and inguinal lymphadenopathy are common. Drainage in the operating room is required so that the entire abscess and fistula network can be evaluated and treated.[35]

Supralevator Abscess. Accounting for less than 5% of abscesses, supralevator abscesses cause perianal and buttock pain associated with fever and leukocytosis. External evidence of this disease usually is absent, which often delays the diagnosis. Approximately 23% of patients with this condition are obese or have diabetes mellitus, and others have concurrent disorders such as Crohn's disease, pelvic inflammatory disease, or diverticulitis. A tender mass may be palpated on rectal or pelvic examination. Emergent surgical treatment is indicated to drain the abscess and excise the fistulous network.[35,39]

Postanal Abscess. Postanal abscesses are uncommon and occur posterior to the rectum, deep to the external sphincter, and inferior to the levator ani. Patients experience severe rectal discomfort and coccygeal pain. They usually are febrile and have continuous pain that does not change with position. Rectal examination is painful, but anal drainage is rare. Many of these abscesses are missed on initial presentation, and the patient may be misdiagnosed as having lumbosacral strain, proctalgia fugax, sciatica, or coccygodynia. Patients often return in a few days with an abscess draining at the skin. Treatment is surgical.

Horseshoe Abscess. Occasionally a large, communicating, horseshoe-shaped abscess forms in the ischiorectal, intersphincteric, or supralevator space. Surgical management is necessary.

Necrotizing Infection. A delay in management of an anorectal abscess may lead to the destruction of tissue, especially in diabetic or immunocompromised patients. Widespread cellulitis, necrotic tissue, and gas on radiography suggest the possibility of necrotizing fasciitis, Fournier's gangrene, or tetanus. Wide surgical débridement, broad-spectrum antibiotics with anaerobic coverage, and tetanus prophylaxis are required.

Treatment of Fistulae

A *fistula* (Latin for "pipe") is a connection between two epithelium-lined surfaces. Anorectal fistulae develop in 50 to 67% of patients with ischiorectal abscesses.[37] Other causes include Crohn's disease, trauma, foreign body reactions, TB, and cancer. Evidence to support these diagnoses should be sought because the anorectal complaint may be the presenting symptom of the underlying disease. Patients notice a recurrent or persistent perianal discharge that becomes painful when one of the openings becomes occluded. Bidigital rectal examination may reveal a tract in the perineum or canal. Probing of fistulous tracts is not recommended because the danger of creating a new tract outweighs the benefit of identifying the path of the existing fistula. Spontaneous resolution of fistula in ano is rare. Although symptoms resolve when antibiotics are administered (e.g., ciprofloxacin, metronidazole), they commonly return as soon as therapy is discontinued. Increasingly, definitive treatment of the fistulous network at the time of incision and drainage of the abscess is advocated to prevent ongoing progression of the disease continuum. Fistulectomy and application of fibrin glue are commonly accepted practices of colorectal surgeons.[35,39,40,41] Nonsurgical treatments that have been proposed for some patients, especially those with Crohn's disease, are administration of infliximab, a monoclonal antibody, or cyclosporine and hyperbaric oxygen therapy.[37]

Pilonidal Disease

Principles of Disease

Little nests of hair in the sacrococcygeal area were first described in 1847 by Anderson (Latin *pilus,* "hair"; *nidus,* "nest"), who originally believed the lesions to be scrofula.[42] More than 150 years later, physicians have yet to agree on the cause and best mode of treatment. Pilonidal abscesses and subsequent sinus tracts afflict young adults with a 4:1 male predominance and are more common in obese and hirsute persons. The disease is rare in people older than 40 years, even among those who were affected in their youth. The lesions arise in the midline of the sacrococcygeal area in the natal cleft and should not be confused with anal fistulae, perirectal abscesses, hidradenitis suppurativa, or granulomatous diseases (syphilis, TB).[43] Much of the current understanding of pilonidal disease comes from the experience in World War II, when the condition was rampant among jeep drivers and was therefore dubbed "jeep-driver's disease."[43,44]

The debate between congenital predisposition and acquired disease seems to favor the latter.[44-46] This theory asserts that bacteria enter the usually sterile hair follicle and produce inflammation and edema, thereby occluding the opening to the skin surface. The contents expand until the hair follicle ruptures, and the material spreads into the subcutaneous fatty tissue, where a foreign body reaction leads to abscess formation. The purulent material subsequently tracks cephalad and drains to the skin through a laterally displaced, epithelialized tract. Diagnosis is made by establishing the presence of a painful, fluctuant area in the presacral skin. In chronic or recurrent disease, visible or palpable tracts 2 to 5 cm in length may be identified with openings approximately 5 cm above the anus. These sinuses usually contain hairs and cellular debris.[43,44]

Management

Treatment options vary, ranging from conservative therapy to extensive surgical excision.[43,44,47] Antibiotics can supplement incision and drainage in cases accompanied by cellulitis but are not effective as the primary mode of treatment. ED management of pilonidal disease involves drainage of the acute abscess for relief of symptoms. To prevent reaccumulation of debris and to minimize inflammation in the midline, a longitudinal incision lateral to the sacral midline should be made. To decrease the usual 40% recurrence rate, the patient can be referred for follicle removal and unroofing of sinus tracts after the acute inflammation subsides (usually 1 week). An alternate noninvasive strategy of shaving the hairs in the natal cleft every 3 weeks has been reported. For patients whose disease is recalcitrant, unroofing and marsupialization or wide excision techniques are used.[47]

Hidradenitis Suppurativa

Perianal hidradenitis suppurativa is an infection of the apocrine glands. It is most common in young adults and is related to poor skin hygiene, hyperhidrosis, obesity, acne, diabetes mellitus, and smoking. The condition commonly is misdiagnosed as pilonidal disease or fistula in ano. Other considerations in the differential diagnosis include sebaceous cysts, furuncles, granulomas (from TB or syphilis), and Crohn's disease. Occluded apocrine ducts may be infected with strains of *Staphylococcus, Streptococcus, E. coli,* or *Proteus.* Extension through the dermis spreads the infection to neighboring ducts, and a network of sinus tracts forms. This cycle leads to extensive scarring.[46,48]

Patients report one or more tender, draining pustules in the perianal area, which may be associated with fever, leukocytosis, and malaise. Local lymphadenopathy and surrounding cellulitis are common. Treatment begins with careful attention to perianal hygiene, warm compresses, and broad-spectrum antibiotics. Recently, infliximab has been found to be effective, resulting in rapid clinical improvement.[49] Drainage of isolated lesions may provide symptomatic relief, but the recurrence rate approaches 40%. Referral to a surgeon for wide excision of tissue involved in advanced chronic disease may be necessary.[50-52]

Proctalgia

Perspective

Anorectal pain (proctalgia) that does not arise from one of the organic disorders described earlier can be severe and difficult to treat.[53,54] The two most common causes are levator ani syndrome and proctalgia fugax. These disorders can be distinguished by their patterns of affliction. Other causes of pelvic pain, such as tumors, cauda equina syndrome, and endometriosis, must be considered.[55]

Levator Ani Syndrome

A constant, dull pressure in the sacrococcygeal region that is precipitated by defecation or prolonged periods of sitting suggests levator ani syndrome. The patient usually has tenderness of the levator muscles, which may be firmly contracted on examination. It affects both men and women. No standard treatment regimen has been studied, but anecdotal reports indicate that sitz baths, levator ani muscle massage, and muscle relaxants can provide some relief.[53,54]

Proctalgia Fugax

Proctalgia fugax is an intensely painful spasm in the rectal area that begins abruptly and lasts for several minutes. It is attributed to a sudden spasm of the levator muscle complex or the sigmoid colon. People who frequently visit the toilet are at greatest risk, and women are more commonly affected than men. A psychogenic predisposition is described by Pilling and colleagues, who found that professionals, managers, and perfectionists are more likely to be affected.[56]

Proctalgia fugax can begin abruptly during sleep, defecation, urination, or intercourse. The nature of the pain has been compared to a "charley horse." It lasts less than 30 minutes and may radiate to the coccyx or perineum. Symptoms during recurrent episodes are consistent for the affected person, and each patient has a unique constellation of symptoms.[53] Treatment often is unrewarding, but recommendations include bowel cleansing regimens, upward manual pressure on the anus, diazepam, and topical nitrates.[54]

Fecal Incontinence

Perspective

Fecal incontinence is an embarrassing condition that affects parous women, elderly persons, and patients with a variety of neurologic or traumatic disorders. The delicate balance among the pelvic floor muscles, sphincters, and anorectal sensation is disrupted in this condition. Complete incontinence is the inability to control passage of solid feces. Partial incontinence is characterized by loss of control of the passage of flatus or liquid feces.

Principles of Disease

Multiple causes of fecal incontinence have been described (Box 96-4).[53,57,58] Injury to muscles and nerves may result from

accidental trauma or surgery for anorectal disorders. Similarly, injury or stretching during childbirth can cause immediate or delayed problems. Spinal cord and cauda equina lesions and the autonomic neuropathy of diabetes mellitus can cause progressive incontinence. Liquid feces may seep around tumors or foreign bodies of the rectum or anal canal. A common "foreign body" is a large impacted stool, as seen in elderly patients or those with underlying megacolon. Explosive diarrhea from laxative abuse, inflammation, or infection can temporarily overwhelm a normal sphincter mechanism. Partial incontinence after surgery to correct imperforate anus is common.[59] Incontinence is a common feature of congenital neurologic conditions such as meningocele, myelomeningocele, and spina bifida. Encopresis also may develop in young children (4 to 7 years) experiencing emotional stress.[60] In otherwise healthy children, sexual abuse involving the anus must be considered.[61]

Clinical Features

The physical examination should address the local and systemic factors described previously. The anorectum should be assessed for masses, hemorrhoids, evidence of previous surgery, and neuromuscular function. The anocutaneous reflex, or "anal wink," is elicited by touching the skin near the anus with a pin and observing the resulting constriction. Sphincter function is assessed by asking the patient to "squeeze" the examiner's finger.

Management

The approach to management of fecal incontinence depends on the cause. Structural and inflammatory conditions may be diagnosed with anoscopy. In cases of transient incontinence caused by diarrhea, a high-fiber diet along with brief therapy with loperamide or opioids has been shown to solidify stool and enhance rectal compliance.[57]

Neuromuscular causes of fecal incontinence can be diagnosed by anorectal physiologic testing. In addition to conservative treatment measures described for transient incontinence, Kegel exercises, biofeedback training, or surgical repair may be necessary.[57,58,62]

Pruritus Ani

Principles of Disease

Patients with pruritus ani complain of an uncontrollable urge to scratch the perianal area. Approximately 1 to 5% of the population seeks medical attention for this condition during their lifetime. Others rely on self-treatment to soothe less severe symptoms. The period of peak incidence is during the fifth and sixth decades of life, and it occurs more often in men. The condition is more common in the summer months and is more noticeable at night. The sensation of itching arises when the richly innervated perianal skin becomes irritated. Patients scratch vigorously in an effort to relieve the itching, creating a vicious circle that results in greater irritation and excoriation. The causes of pruritus ani are summarized in Box 96-5.

The most common cause is the presence of feces on the perianal skin. Conditions ranging from poor personal hygiene to anatomic disorders of the anorectum allow feces to accumulate in the area. Patients may not clean the area thoroughly after defecation. Disruptions in the anorectal anatomy can lead to uncontrollable fecal accumulation on the perianal skin. Obesity, deep perianal clefts, copious hair, hemorrhoids, posthemorrhoidal skin tags, rectal

www.ketabpezeshki.com 66485457-66963820

mucosal prolapse, anal fissures, and fistulae make the area difficult to clean effectively. Decreased air circulation from wearing tight pants or undergarments of synthetic "nonbreathable" fabric may exacerbate symptoms.[63]

Foods (e.g., caffeine, spicy or citrus foods, tea, beer) and drugs (e.g., quinidine, colchicine, tetracycline, intravenous hydrocortisone) augment the irritant quality of the feces by altering its pH. Perfumed soaps and drugs, especially local anesthetic creams and ointments, can produce a contact dermatitis. Prolonged use of hemorrhoidal preparations containing local anesthetic and topical corticosteroid can exacerbate the symptoms. Other dermatologic conditions include psoriasis, seborrhea, lichen simplex, and lichen sclerosus.

Systemic diseases and local infections can produce perianal itching. Chronic renal failure, diabetes mellitus, thyrotoxicosis, myxedema, polycythemia vera, deficiency of iron or vitamin A or D, and certain cancers (Bowen's disease, Paget's disease, Hodgkin's disease) are systemic causes. Local conditions include pinworms (*Enterobius vermicularis* infection), scabies (*Sarcoptes scabiei* infection), bacterial or fungal infections, and dermatologic manifestations of sexually transmitted diseases (STDs) (e.g., syphilis or herpes simplex virus [HSV], cytomegalovirus, or human papillomavirus infection).

Management

A careful history and physical examination can identify the cause of pruritus ani. Important considerations include hygienic care of the anus, coexisting anorectal or systemic conditions, diet, and sexual practices.

Pinworms can be identified by applying transparent tape to the perianal area and attaching it to a glass slide. Visualization of eggs under the low-power objective of a microscope confirms the diagnosis. The first-line agent is mebendazole (Vermox) 100 mg orally. An alternative agent is pyrantel pamoate (Antiminth) 1 g orally (11 mg/kg, to a maximum of 1 g for pediatric patients). The dose of either may need to be repeated in 2 weeks. Scabies and pediculosis pubis should be treated with 1% lindane lotion or 5% permethrin cream. Dermatitis caused by a fungal infection is characterized by sharply demarcated borders and is treated with clotrimazole or nystatin cream. Definitive treatment of concomitant anorectal conditions (e.g., fissures, fistulae, hemorrhoids, skin tags, rectal prolapse) can prevent recurrence of pruritus ani.[64]

Underlying systemic diseases that have perianal manifestations should be treated. Education on personal hygiene is of the utmost importance. Patients should be instructed to clean the area thoroughly with lukewarm water after each bowel movement and pat (rather than rub) it dry with a tissue or towel that is free of chemical irritants. Loose-fitting underwear and exposure to fresh air may aid in alleviating symptoms. The treatment of acute dermatitis includes a short course of topical corticosteroids,[65] calamine lotion, and systemic antihistamines. Some success with topical application of capsaicin cream has been reported.[62,66] Prevention of recurrent bouts of pruritus ani requires compliance with impeccable anal hygiene and minimizing the factors that caused the initial exacerbation.[63]

SEXUALLY TRANSMITTED DISEASES AND PROCTITIS

General Approach

Anorectal transmission of STDs is of particular concern in the patient with HIV infection. For patients who are sexually active, the history should ascertain whether sexual practices involve anal penetration and whether condoms are used. As a means of public health prevention of disease and patient safety, education regarding transmission of STDs and the efficacy of barrier methods is important.[67-69] Semen has a concentrated viral load, and the damaged epithelium of ulcerated anoderm makes an easy portal for entry of the virus. Syphilis, gonorrhea, and chlamydial infection have been documented among men who have sex with men. For this reason, routine STD screening is indicated.[67] A summary of common infections and treatment guidelines is presented in Table 96-5.

Surgical repair for benign anorectal conditions in HIV-positive patients should be undertaken early in the course of the disease, when potential wound healing and overall patient health are at their best.[68] Empirical therapy is indicated for patients who have recently practiced anal-receptive intercourse and have a rectal discharge. The recommended regimen is a single dose of ceftriaxone 250 mg intramuscularly plus doxycycline 100 mg twice a day orally for 7 days.[67] Patients with anorectal infections should be referred for HIV testing. The possibility of sexual assault should be considered and managed appropriately.[67] The health care provider should report STDs and new diagnoses of HIV infection in accordance with state and local health department regulations.

Treatment of Specific Sexually Transmitted Diseases

Gonorrhea

Gonorrhea is caused by the gram-negative diplococcus *Neisseria gonorrhoeae.* Proctitis (inflammation of the rectum) results from anal intercourse or autoinoculation from vaginal secretions and becomes symptomatic after a 5- to 7-day incubation period. Symptomatic patients report pruritus ani, tenesmus, and bloody or thick, purulent yellow drainage. Anoscopy reveals proctitis and mucus in the anal crypts. Recovery of the organism directly from the crypts doubles the likelihood of identifying the organism on Gram stain. Water should be used to lubricate the anoscope because many lubricants contain an antibacterial agent. Signs and symptoms of disseminated gonococcal infection may include arthritis, skin lesions, perihepatitis, endocarditis, and meningitis.[70]

Chlamydial Infection and Lymphogranuloma Venereum

Infection with *Chlamydia trachomatis,* an intracellular organism that is endemic to the tropics, is a common STD in the United States.[67,70] It causes proctitis in people whose sexual practices include anal intercourse or oral-anal contact. Common signs and symptoms include mucoid or bloody rectal discharge and tenesmus. Some people are asymptomatic carriers of the organism. Lymphogranuloma venereum is a more serious manifestation caused by specific strains of *C. trachomatis* and starts as a painful anal or perianal ulceration. Prominent unilateral lymph nodes coalesce to form a bubo, which must be distinguished from the granuloma of secondary syphilis. Patients often have systemic complaints of fever and malaise. Anoscopic examination reveals an erythematous, friable mucosa. Rectal cultures generally are unreliable because the organism is intracellular. Diagnosis is best achieved by immunofluorescent antibody testing. In the final stage, rectal strictures and rectovaginal fistulae may form.[70]

Herpes Simplex Virus Infection

Herpes proctitis is caused by both HSV-1 and HSV-2, but HSV-2 is responsible for approximately 90% of cases, especially in the HIV-positive population.[67,70] Herpes genital infections occur in people whose sexual practices include oral-anal contact or anal

Table 96-5 Sexually Transmitted Diseases of the Anorectum

DISEASE OR CONDITION (WITH SPECIFIC PATHOGEN WHEN KNOWN)	FINDINGS	TREATMENT
Ulcerative Conditions		
LGV	Unilateral inguinal adenopathy Fever, malaise Mucoid or bloody discharge	Doxycycline 100 mg PO bid × 21 days *For pregnant patients or those allergic to tetracyclines*: Erythromycin 500 mg PO qid × 21 days
HSV infection	Rectal pain, tenesmus, constipation Bloody mucoid discharge Vesicles and ulcerations Fever, malaise, myalgias, paresthesias	*First episode*: Acyclovir 400 mg PO tid 7-10 days *or* Acyclovir 200 mg PO 5×/day × 7-10 days *or* Famciclovir 250 mg PO bid × 7-10 days *or* Valacyclovir 1 g PO daily for 7-10 days
Early (primary) syphilis *(Treponema pallidum)*	Chancre Tenesmus, pain, mucoid drainage Inguinal lymphadenopathy	Benzathine penicillin G 2.4 million units IM once
Chancroid *(Haemophilus ducreyi)*	Inflammatory lesion progresses to ulcer Inguinal adenitis—bubo	Azithromycin 1 g PO once *or* Ceftriaxone 250 mg IM once *or* Ciprofloxacin 500 mg PO bid × 3 days *or* Erythromycin 500 mg PO tid × 7 days
Idiopathic (usually HIV positive)	Eccentric, deep, poor healing, multiple lesions	Symptomatic relief or surgical referral
Nonulcerative Conditions		
Condylomata acuminata (HPV)	Keratinized vegetative growths in anus or skin Asymptomatic, or pruritus ani, or bleeding	Podofilox 0.5% topically, or cryotherapy
Gonorrhea *(Neisseria gonorrhoeae)*	Pruritus ani Tenesmus Purulent yellow discharge	Ceftriaxone 250 mg IM once *or* cefixime 400 mg PO once
Chlamydial infection *(Chlamydia trachomatis)*	Mucoid or bloody discharge Tenesmus	Azithromycin 1 g PO once *or* Doxycycline 100 mg PO twice per day × 7 days
Syphilis (secondary)	Maculopapular rash Condyloma latum	Benzathine penicillin G 2.4 million units IM once

HIV, human immunodeficiency virus; *HPV,* human papillomavirus; *HSV,* herpes simplex virus; *IM,* intramuscularly; *LGV,* lymphogranuloma venereum; *PO,* orally.

intercourse. Symptoms appear 1 to 3 weeks after exposure. Those with proctitis may have severe rectal pain, bloody mucoid discharge, tenesmus, constipation, sacral paresthesias, or urinary difficulties. Systemic complaints may include fever, malaise, and myalgias. Physical examination and anoscopy may be impossible without anesthesia. Single or coalesced vesicles and ulcerations occur in the perianal area and rectum, and anoscopy reveals an erythematous, friable, ulcerated rectal mucosa. Chronic mucocutaneous HSV infection is considered diagnostic for AIDS. Definitive diagnosis with viral or immunofluorescent staining relies on proper collection of fluid and scrapings from the base of the vesicle.[67,70]

Syphilis

Syphilis is caused by *Treponema pallidum,* a motile spirochete. During anal intercourse, the organism enters the rectal mucosa or anoderm and forms an ulcer (chancre) within 2 to 6 weeks. The chancre heralds the primary phase of syphilis and may resemble an anal fissure. Patients may experience discomfort during defecation, tenesmus, mucoid discharge, and inguinal adenopathy. Primary syphilis can be confused with lymphoma, but the diagnosis can be made by visualizing spirochetes on darkfield microscopy from scrapings taken from the base of the ulcer.[70] Serologic testing is useful several weeks after the appearance of the chancre. Treponemal tests such as the fluorescent treponemal antibody test yield a positive result earlier than does the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (nontreponemal) test. Patients with AIDS have a high incidence of neurosyphilis regardless of the stage of syphilis at the time they seek treatment.[71]

If the chancre goes unnoticed, patients may have secondary syphilis on presentation, marked by a maculopapular rash that characteristically involves the palms and soles. Condyloma latum is a spirochete-laden, weeping, verrucous lesion in the perianal area that emits a foul odor. It is easily distinguishable from condyloma acuminatum, which has a drier, more keratinized appearance. Serologic testing results usually are positive. Tertiary syphilis is rare but may manifest as a rectal gumma with severe perianal pain and paralysis of the sphincters, which may be mistaken for anal cancer.[67]

Chancroid

Chancroid is caused by the gram-negative bacillus *Haemophilus ducreyi* and begins as an inflammatory pustule or macule that ruptures to form an irregularly shaped ulcer. In several days, painful inguinal adenitis develops. Chancroid often is a diagnosis of exclusion.

Condyloma Acuminatum

Condyloma acuminatum, the most commonly encountered anorectal STD, is caused by human papillomavirus. These lesions, also called *genital warts,* most often are found in homosexual men but can be seen in heterosexual men, women, and children. The mode

of transmission is primarily through sexual intercourse, but transmission can occur through close personal contact, as often happens in pediatric cases in which an infected person is changing a diaper and transmits the virus to the infant because of poor handwashing techniques. It is incumbent on the evaluating physician to consider sexual abuse in such cases.[21] Because one half of HIV-positive patients have anal warts, HIV testing is recommended in patients with this diagnosis.[67]

The pink-to-gray warts are a result of hyperplastic epithelial growth and appear as vegetative papilliform growths (Fig. 96-7). They may coalesce to form a massive patch that obscures the anal verge.[33] Many patients are asymptomatic or report pruritus ani, a "hemorrhoid," or bleeding. Evaluation should include anoscopy because the warts often grow within the anal canal. Failure to treat the internal lesions results in recurrence.[67,70] The differential diagnosis includes the condyloma latum of secondary syphilis and squamous cell carcinoma. Progression to intraepithelial neoplasia has been reported to be related to the level of immunosuppression. Preferred treatment is cryotherapy, but outpatient treatment with 0.5% podofilox solution or gel can be successful in limited cases.[67]

Ulcerative Lesions in the Patient with HIV Infection

The practice of anal intercourse has led to a proliferation of anorectal STDs. Most patients who are HIV seropositive have current or past infection with an STD, which may be the initial reason for seeking medical attention. One third of anorectal complaints in this population fall into three categories: (1) routine proctologic conditions as seen in the general population, (2) STDs, and (3) opportunistic infections (Box 96-6). The treatment of routine conditions and common STDs is similar to that in other patients except that wound healing may be slower in HIV-infected patients.

In immunocompromised patients, the differential diagnosis of ulcerative anorectal lesions should include opportunistic infections, lymphoma, and Kaposi's sarcoma. Patients with AIDS often exhibit idiopathic anal ulcerations with pain and bleeding. Before this diagnosis is made, other possible causes of the lesions must be considered (see Box 96-6). Symptomatic relief can often be achieved with the WASH regimen (see Box 96-2), but recalcitrant lesions may require surgical excision.[67,70]

Radiation Proctitis

Radiation-induced injury of the rectum is often caused by treatment of gynecologic, urologic, and GI malignancies. Immediate radiation proctitis usually is self-limited and responds to symptomatic treatment. Delayed radiation proctitis can manifest up to 2 years after the exposure to radiation and may predispose the patient to subsequent rectal malignancies as a result of damage to DNA.

Signs and symptoms of radiation proctitis include bleeding ranging in severity from spotting to hemorrhage, tenesmus, diarrhea, pain, fistula in ano, and rectal strictures. Diagnosis is achieved by rectal mucosal biopsy, a procedure best performed with the patient under sedation or anesthesia.

Treatment regimens include the use of anti-inflammatory agents, botulinum toxin injection, enemas with short-chain fatty acids, oral sucralfate therapy, hyperbaric oxygen therapy, and sclerosing therapy.[72-75] Supportive therapy can be given for symptoms that the individual patient experiences.

Procidentia

Rectal prolapse, or procidentia, is a disease of persons at the extremes of age. Prolapse is *complete* if all bowel layers protrude and *incomplete* if only the mucosal layer is involved. In adults, complete procidentia is most common among older women with a history of excessive straining while defecating. The cause is a laxity of attachment structures, and the rectal prolapse often is accompanied by uterine prolapse or cystocele. Patients report an anal mass that protrudes during defecation, coughing, or sneezing. Findings may include fecal incontinence, bloody or mucoid discharge, and a foul odor. In some cases the patient is able to reduce the prolapse manually, whereas in others the tissue becomes edematous and a red, ulcerated mass protrudes from the anus (Fig. 96-8). Sphincter tone may be weakened. Reduction may be attempted; when this is successful, the patient should be discharged with agents to relieve constipation. Surgical repair often is necessary.[76,77]

In children up to 4 years of age, procidentia often is associated with chronic constipation or diarrheal disease. However, it may herald the presence of malnutrition, parasitic infection, or cystic fibrosis.[78] Children usually have a mucosal prolapse. The parent reports protrusion during defecation with small amounts of mucus or blood. This condition must be distinguished from a protruding juvenile polyp and intussusception. Gentle reduction may be attempted. Conservative medical management aimed at the cause of procidentia often is successful because of the self-limited nature of the condition in children. Increasing the dietary fiber and fluid intake frequently is successful as a first line of therapy.[77,78]

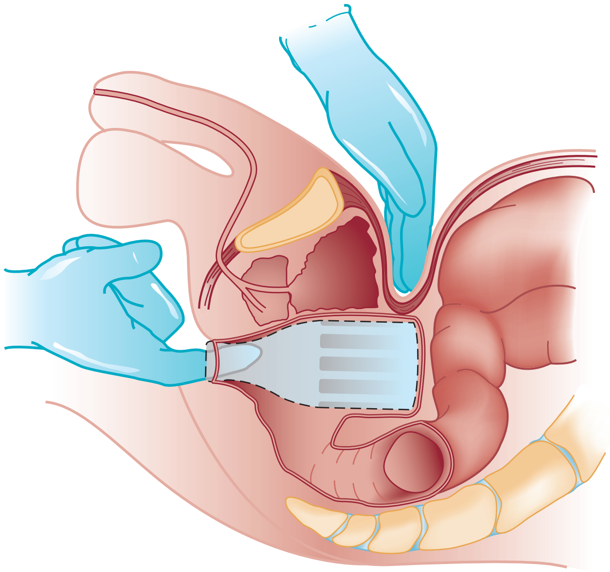

Figure 96-9. Removal of a foreign body from the rectum.

Anorectal Foreign Bodies

Perspective

Anorectal foreign bodies may result from the use of the anus for sexual gratification, although they also are found in children, psychiatric patients, and victims of assault or iatrogenic injury. Most objects are introduced directly into the anus, but some become lodged there after oral ingestion. It is important to identify and remove foreign bodies to prevent mucosal lacerations, intestinal perforation and obstruction, sepsis, and peritonitis.[79,80] In many cases, removal can be done safely in the ED.

Clinical Features

Objects Inserted into the Anus. Rarely, a foreign body such as an enema tip or broken rectal thermometer is introduced iatrogenically. In most cases the foreign body is placed deliberately by the patient or a partner for medicinal or sexual purposes. Objects that are commonly retrieved include fruits and vegetables; household items, especially those whose dimensions resemble the penis; and items purchased specifically with an anal erotic intent.[80,81] By the time patients arrive at the ED, sometimes days after the introduction of the foreign body, they have likely tried to remove it at home. The history of the injury often is reluctantly given or is vague and inconsistent. The initial ED evaluation, conducted in a nonjudgmental manner, attempts to ascertain the type of foreign body involved, how long it has been there, what attempts have been made to remove it, and whether the patient has fever, abdominal pain, or rectal bleeding. The possibility of assault should be considered.[81]

Physical examination of the anorectum begins with an external examination for signs of trauma followed by digital rectal examination and anoscopy, which may reveal the foreign body, a lax sphincter, or a mucosal injury. Abdominal examination may demonstrate signs of perforation or obstruction. The foreign body may be visible on abdominal radiographs, or its presence may be inferred by a nonspecific gas pattern, free air, or signs of intestinal obstruction.[80] If perforation is suspected, water-soluble contrast material can be introduced to delineate radiolucent foreign bodies.

Orally Ingested Foreign Bodies. Some foreign bodies that are ingested orally, especially toothpicks and fish or chicken bones, pass through the GI tract and subsequently become lodged in the rectum or anal crypts.[81] Patients at highest risk for ingested foreign bodies are children, especially those in the first 2 years of life; psychiatric patients; and body packers who ingest condoms containing drugs.

Management

Optimal treatment depends on the location and type of object found.[79] In general, objects that are soft and low-lying (less than 10 cm from the anal verge) can be removed safely in the ED. Large, hard, fragile objects and those that have migrated proximally are difficult to remove without anal dilation and instrumentation to assist in the passage through the sacral curve and sphincters. These are best performed with the patient under general anesthesia.[82] As a rule, however, the patient should remain awake to assist in expulsion by performing the Valsalva maneuver at the appropriate time, and premedication with a benzodiazepine is helpful to relax both the sphincter and the patient.[81] With the patient in the lithotomy position, suprapubic pressure can assist in removal (Fig. 96-9). Other positions may be more appropriate for a particular foreign body.

Several methods are effective for removal. The easiest is to grasp an edge of the foreign body with forceps and apply traction while the patient bears down. Most foreign bodies in the rectum do not have a convenient place to grasp, and other methods are needed. A Foley catheter can be placed beside the foreign body and the balloon inflated proximal to it (Fig. 96-10). This breaks the suction of the rectal wall mucosa and provides a way to guide the object out of the rectal vault. Hollow objects may be filled with plaster of Paris, with an inset, inflated Foley catheter to be used as a handle.[81]

Other creative ways to remove foreign bodies in the ED have been successful, and an individualized strategy for each patient is essential. After the removal of the foreign body, all patients should undergo sigmoidoscopy to look for mucosal tears and perforations. Discharge instructions should warn the patient about signs and symptoms of perforation, peritonitis, and sepsis.[80]

www.ketabpezeshki.com 66485457-66963820

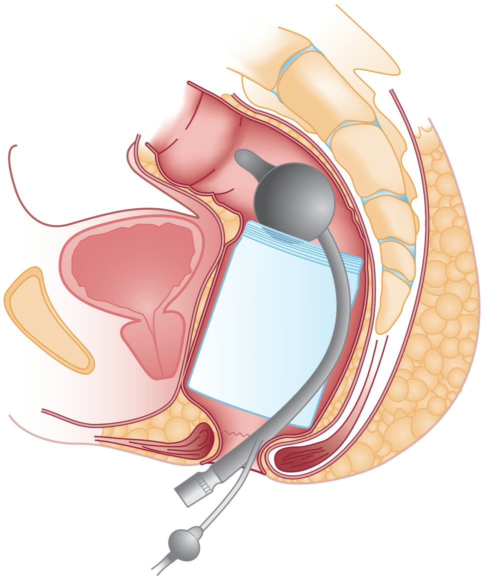

Figure 96-10. Foley catheter–assisted removal of a rectal foreign body.

KEY CONCEPTS

- Patients who seek treatment for nonspecific anorectal complaints should be evaluated for the presence of underlying systemic disease (e.g., cancer, diabetes mellitus, immunodeficiency) because disorders of the anus may herald associated conditions.
- Patients with any STD should be evaluated for HIV infection and questioned about the use of the anus for sexual purposes.
- Anorectal conditions can be differentiated according to an algorithm (see Fig. 96-2) that addresses the presence or absence of pain, bleeding, swelling, and pruritus, in combination with an assessment of the patient's overall health.
- Most anorectal conditions can be symptomatically improved by adherence to the WASH regimen (warm water, analgesics, stool softeners, high-fiber diet).

Section Six

GENITOURINARY AND GYNECOLOGIC SYSTEMS

Chapter 97

Renal Failure

Allan B. Wolfson

EVALUATION OF RENAL FUNCTION

The evaluation of renal disease in the emergency department (ED) requires the intelligent use of urinalysis, serum and urine chemical determinations, and renal imaging studies to assess the degree of renal dysfunction and to take the first steps in determining its cause.

Diagnostic Strategies

Urine Volume

Because urine flow does not diminish until the glomerular filtration rate (GFR) is sharply decreased, urine volume is a poor indicator of renal dysfunction. In fact, urine volume often *increases* as concentrating ability is lost with advancing renal dysfunction; patients with renal failure typically produce urine that is isosmolar with serum. *Oliguria,* defined as a urine volume of 100 to 400 mL/24 hr, may be seen with prerenal (blood flow dependent), intrinsic (intrarenal), or postrenal (obstructive) causes of acute kidney injury (AKI) (previously known as *acute renal failure* [ARF]). Although uncommon, alternating oliguria and anuria (the latter defined as less than 100 mL/24 hr), is a classic indicator of intermittent obstruction, which occurs as urine collects behind an obstructing stone or tumor and then is allowed to flow past as the obstructing material shifts position.

Urinalysis

The standard urinalysis consists of dipstick screening for heme pigment, protein, glucose, ketones, pH, leukocyte esterase, and nitrite and microscopic examination of a spun specimen of freshly voided urine.

Heme

The dipstick detects both free hemoglobin from lysed red blood cells (RBCs) (or myoglobin) and the hemoglobin inside RBCs but is more sensitive to free hemoglobin. Although as few as three RBCs per high-power field can be detected, on any given sample the dipstick may fail to identify 10 to 15% of patients who are otherwise found to have microscopic hematuria, as defined by more than five RBCs per high-power field. A positive result on dipstick testing should prompt microscopic examination of the urine. If red cells are seen, the diagnosis of hematuria is confirmed. If the dipstick result is positive but findings on microscopic examination are negative, pigmenturia (myoglobin or free hemoglobin) is suspected as a potential cause.

Protein

The dipstick test for protein, which uses the color change of tetrabromophenol blue, can detect protein at concentrations of 10 to 15 mg/dL but does not yield reliably positive results until the concentration is greater than 30 mg/dL. Moreover, the relation between color intensity and protein concentration is only approximate. The dipstick reagent is three to five times more sensitive to albumin than to globulins and immunoglobulin light chains (e.g., Bence Jones protein)—an important limitation.[1] False-positive results are caused by alkaline urine, hematuria, or prolonged immersion of the dipstick in the urine. False-negative results are seen with dilute urine.

Microscopic Examination

After dipstick testing of the urine has been completed, 10 mL of urine is placed in a conical test tube and spun at 2000 revolutions per minute for 5 minutes (higher speeds may break up casts). The supernatant is discarded. The sediment is resuspended in the residual urine, and a drop is placed on a slide and covered with a coverslip. Observations are recorded as the number of cells per high-power field. A level of two to three RBCs per high-power field in adult men or two to four RBCs per high-power field in adult women is commonly accepted as normal; in many studies a finding of five RBCs per high-power field is considered to represent the threshold of abnormality.[2]

Casts are formed from urinary Tamm-Horsfall protein, a product of the tubular epithelial cells that gels at low pH and high concentration and when mixed with albumin, or from red cells, tubular cells, or cellular debris in the urine. The composition of a cast thus reflects the contents of the tubule. Casts are described and classified according to their appearance or constituents (e.g., hyaline, red cell, white cell, granular, or fatty casts). Hyaline casts, those that are devoid of contents, are seen with dehydration, after exercise, or in association with glomerular proteinuria. Red cell casts indicate glomerular hematuria, as seen in glomerulonephritis; the presence of even a few red cell casts is significant. White cell casts imply the presence of renal parenchymal inflammation. Granular casts are composed of cellular remnants and debris. Fatty casts, like oval fat bodies, generally are associated with heavy proteinuria and nephrotic syndrome.

Microscopic examination of the urinary sediment can be helpful in establishing the cause of AKI. A sediment without

www.ketabpezeshki.com 66485457-66963820

formed elements or with only hyaline casts is characteristic of prerenal azotemia or obstruction. Red cell casts suggest glomerulonephritis or vasculitis. Fatty casts also suggest glomerular disease. In acute tubular necrosis (ATN), the urinary sediment commonly shows granular casts and renal tubular epithelial cells. Large numbers of polymorphonuclear leukocytes are observed in interstitial nephritis, papillary necrosis, and pyelonephritis. Eosinophil-containing casts (appreciated only after staining of the sediment) are typical of allergic interstitial nephritis. Uric acid crystals suggest uric acid nephropathy but are extremely nonspecific; oxalic acid or hippuric acid crystals may be seen in ethylene glycol ingestion.

Serum and Urine Chemical Analysis

Creatinine and Blood Urea Nitrogen. The normal range for the serum creatinine level extends from 0.5 mg/dL in thin people to 1.5 mg/dL in muscular persons. Spurious elevations (up to 2 mg/dL) can be caused by acetoacetate (which cross-reacts with creatinine in commonly used assays) as well as by certain medications that either cross-react in the assay or reversibly inhibit tubular creatinine secretion despite a normal GFR (generally less than 0.5 mg/dL). Serum creatinine concentration is a function of the amount of creatinine entering the blood from muscle, its volume of distribution, and its rate of excretion. Because the first two are usually constant, changes in serum creatinine concentration generally reflect changes in GFR. The creatinine clearance is commonly estimated by the Cockcroft-Gault equation[3]:

$$\text{Creatinine clearance (mL/min)} = \frac{(140 - \text{age}) \times \text{weight}}{72 \times \text{serum creatinine}} \times (0.85 \text{ if female})$$

Table 97-1 Typical Urinary Findings in Prerenal Azotemia and Acute Tubular Necrosis

LABORATORY TEST FINDING	PRERENAL AZOTEMIA	ACUTE TUBULAR NECROSIS
Urinalysis	Normal or hyaline casts	Brown granular casts, cellular debris
Urine sodium concentration (mEq/L)	<20	>40
Fractional excretion of sodium (%)	<1	>1
Urine-to-plasma creatinine ratio	>40	<20

Box 97-1 Causes of High or Low FENa and UNa in Patients with Acute Kidney Injury

UNa <20 mEq/L, FENa <1%	UNa >40 mEq/L, FENa >1%
Prerenal azotemia	ATN (90% of cases)
Acute glomerulonephritis	Chronic obstruction
Acute obstruction	Diuretic drugs
Contrast-induced ATN (some cases)	Osmotic diuresis
Rhabdomyolysis-associated ATN (some cases)	Underlying chronic renal failure
Early sepsis	
Nonoliguric ATN (10% of cases)	

From Kelley WN (ed): Internal Medicine, 2nd ed. Philadelphia, JB Lippincott, 1992.
ATN, acute tubular necrosis; *FENa,* fractional excretion of sodium; *UNa,* urine sodium concentration.

Under steady-state conditions, if the GFR is halved, the serum creatinine doubles. Abrupt cessation of glomerular filtration causes the serum creatinine to rise by 1 to 2 mg/dL per day. Thus a daily increment of less than 1 mg/dL suggests that at least some renal function has been preserved. Rhabdomyolysis releases creatine into the plasma and may cause the serum creatinine to increase by more than 2 mg/dL per day. The blood urea nitrogen (BUN) level also rises with renal dysfunction but is influenced by many extrarenal factors as well. Increased protein intake, gastrointestinal (GI) bleeding, and the catabolic effects of fever, trauma, infection, and drugs such as tetracycline and corticosteroids all increase protein turnover and result in increased hepatic urea production and increased BUN. Conversely, BUN tends to be decreased in patients with liver failure or protein malnutrition.

When glomerular filtrate has been formed, renal urea clearance is largely a function of flow rate. Urea clearance is thus decreased in patients with prerenal azotemia or acute obstruction, despite preservation of tubular function. In such cases the BUN/creatinine ratio usually is greater than the normal value of 10 : 1, whereas this ratio usually is not markedly increased in cases of uncomplicated intrinsic AKI.

Urine Sodium and Fractional Excretion of Sodium. Measurement of the urine sodium concentration provides information on the integrity of tubular reabsorptive function. Normally, urine sodium concentration parallels sodium intake. Low urine sodium concentration thus indicates not only intact reabsorptive function but also the presence of a stimulus to conserve sodium. The urine sodium concentration, as well as the fractional excretion of sodium (FENa), an additional measure of tubular sodium handling, helps distinguish between the two most common causes of AKI: prerenal azotemia and ATN (Table 97-1).

Urinary indices are most helpful in oliguric patients.[4] In general, an oliguric patient with a urine sodium concentration below 20 mEq/L and an FENa below 1% should be considered to have prerenal azotemia, whereas urine sodium concentration above 40 mEq/L and FENa above 1% suggest ATN. Values in patients with prerenal azotemia overlap somewhat with those in patients with nonoliguric ATN, particularly if the renal injury is mild and some capability to retain sodium has been preserved. Thus, intermediate values for urine sodium concentration and FENa are of little help in differentiating between the two conditions. The administration of mannitol or a loop diuretic within the several hours preceding urine collection also may make interpretation of urine values difficult because the urinary sodium will tend to be higher and the urine less concentrated, causing the results in prerenal azotemia to resemble those in intrinsic renal failure (Box 97-1).

In glomerulonephritis, the urinary indices generally reflect intact tubular sodium handling, but the diagnosis is more accurately made by urine microscopy. In obstructive uropathy, the values of the urinary indices depend on the duration of obstruction and cannot be relied on to indicate either the presence or absence of obstruction.

Renal Imaging

Renal imaging is often helpful in evaluation of the patient with kidney dysfunction, particularly when obstruction is suspected. Contrast-enhanced computed tomography (CT) scanning provides an anatomic image of the urinary tract but does not provide an evaluation of renal function. The classic CT findings of obstruction are kidneys that are normal to large in size, nephrograms that become increasingly dense, and delayed opacification of dilated collecting systems. However, contrast-enhanced CT subjects the kidneys of an already azotemic patient to the risk of an additional potential insult from the contrast agent. Thus techniques such as

www.ketabpezeshki.com 66485457-66963820

Figure 97-1. Computed tomography scan of bilateral hydronephrotic kidneys without intravenous contrast medium.

Box 97-2 Causes of Hematuria

Hematologic Causes
Coagulopathy
Sickle hemoglobinopathies

Renal Causes
Glomerular
Primary glomerular disease
Multisystem disease (e.g., systemic lupus erythematosus, Henoch-Schönlein purpura, hemolytic uremic syndrome, polyarteritis nodosa, Wegener's granulomatosis, Goodpasture's syndrome)

Nonglomerular
Renal infarction
Tuberculosis
Pyelonephritis
Polycystic kidney disease
Medullary sponge kidney
Acute interstitial nephritis
Tumor
Vascular malformation
Trauma
Papillary necrosis

Postrenal Causes
Stones
Tumor of ureter, bladder, urethra
Cystitis
Benign prostatic hypertrophy
Prostatitis, urethritis
Foley catheter placement
Exercise
Tuberculosis

ultrasonography and CT that do not involve contrast administration are much preferred in patients with preexisting renal insufficiency (Fig. 97-1).

Computed Tomography. Noncontrast CT may be useful in evaluating some azotemic patients. Hydronephrosis can be recognized without the use of contrast material. Often, dilated ureters also can be seen without contrast enhancement, and the level of obstruction can be determined. Moreover, the cause of obstruction (e.g., bilateral stones, lymphoma, retroperitoneal hemorrhage, metastatic cancer, retroperitoneal fibrosis) often can be delineated as well. Occasionally, obstruction severe enough to result in renal failure may not cause detectable proximal dilation of the urinary tract. Bilateral ureteral obstruction produced by malignancy or retroperitoneal fibrosis is the most important cause of this nondilated obstructive uropathy. When noninvasive studies yield negative results, the diagnosis of obstruction can be made by retrograde pyelography or by antegrade pyelography performed via a percutaneous nephrostomy.

Ultrasonography. Ultrasonography allows accurate measurement of renal dimensions and is a safe and reasonably reliable method of excluding obstruction as a cause of AKI. The normal kidney shows an echo-free renal parenchyma surrounding the echogenic central urothelium of the renal pelvis and calices. The sonographic appearance of the kidney in obstruction is that of an enlarged central sonolucent area that spreads the normal central echo densities. A similar pattern may be produced by renal cysts, but without associated ureteral dilation. Dilation of the collecting system generally is apparent within 24 to 36 hours of the onset of obstruction, but obstruction may not be evident in patients who are evaluated early in the development of obstructive AKI.

HEMATURIA AND PROTEINURIA

Hematuria

Principles of Disease

Microscopic hematuria often is discovered incidentally on routine urinalysis, but as little as 1 mL of blood in 1 L of urine can cause grossly appreciable hematuria. Although not invariably a sign of disease, the finding of hematuria calls for an effort to rule out any treatable underlying disorder. Both gross and microscopic hematuria are caused by similar disorders, but the amount of blood in the urine does not correlate with the severity or the seriousness of the underlying condition.[2]

The causes of hematuria can be divided into hematologic, renal, and postrenal; renal causes may be further classified as glomerular or nonglomerular (Box 97-2). Overall, the most common causes of nontraumatic hematuria, in roughly descending order of occurrence, are kidney stones, urinary tract infection (UTI), carcinoma of the kidney or bladder, urethritis, benign prostatic hypertrophy, and glomerulonephritis. The scope of the differential diagnosis can be narrowed by taking into account the patient's age and sex and by distinguishing between upper and lower urinary tract sources. When gross hematuria is present, cystoscopy can determine whether blood is emerging from one or both ureteral orifices, thereby defining a source in the upper tract. Red cell casts indicate a renal source, as does associated proteinuria (excretion of more than 500 mg of albumin in 24 hours). In differentiating between proteinuria from renal parenchymal disease and that simply produced by admixture of urine with extravasated blood, a useful rule of thumb is that 1 mL of whole blood contains approximately 5 billion RBCs and approximately 50 mg of albumin.

ED evaluation of the patient with gross or microscopic hematuria should begin with a complete history to define the pattern and character of the hematuria. Blood noted only on initiation of voiding suggests a urethral source, whereas blood noted only in the last few drops of urine suggests a prostatic or bladder neck source. Hematuria present throughout urination suggests a source in the bladder, ureter, or kidney. Brown or smoky-colored urine usually has a renal source. Blood clots indicate a nonglomerular renal or lower urinary tract source of bleeding. Hematuria may rarely be cyclic or associated with menses, suggesting endometriosis of the ureter or bladder. Flank pain suggests calculus, neoplasm, renal infarction, obstruction, or infection as the cause. Symptoms of frequency, dysuria, and suprapubic pain suggest cystitis or urethritis; in adult men, perineal pain, dysuria, and terminal hematuria suggest prostatitis.

Other clues to the cause are obtained by careful questioning. Because glomerulonephritis or interstitial nephritis may be caused by a variety of bacterial, viral, and parasitic infections, a history of recent infection is important. Symptoms suggestive of a multisystem disorder (e.g., systemic lupus erythematosus) also should be sought, as should a history of human immunodeficiency virus infection.[5] Because drugs may cause acute interstitial nephritis (AIN), papillary necrosis, or hemorrhagic cystitis, a complete

www.ketabpezeshki.com 66485457-66963820

medication history is elicited. When hematuria is associated with anticoagulant use, significant underlying disease can be identified in about one third of patients.[6] The family history may provide a clue to the presence of polycystic or other familial kidney disease, sickle cell disease, or renal calculi. A history of recent strenuous exercise is important to identify; 15 to 20% of normal persons exhibit hematuria after strenuous exercise. The mechanism is unclear, but the hematuria resolves spontaneously within a few days.

Clinical Features

On physical examination, findings of arthritis, skin lesions, hypertension, or edema suggest underlying glomerulonephritis. Examination of the external genitalia may reveal a urethral meatal lesion that may be the source of bleeding; in adult women, a pelvic examination will reveal vulvovaginal sources of blood. Because endocarditis or atrial fibrillation may cause renal embolism, the patient should be checked for a new heart murmur or an irregular rhythm. Costovertebral angle tenderness suggests pyelonephritis or obstructive stone disease, and a palpably enlarged kidney suggests polycystic kidney disease or renal malignancy. The prostatic examination may offer clues to the presence of prostatitis, benign prostatic hypertrophy, or cancer.

Laboratory Findings

Evaluation of hematuria in the ED setting includes assessment of the blood pressure and measurement of the BUN and serum creatinine levels to gauge the patient's underlying renal function, but urinalysis can be expected to provide more specific information. Red or orange urine that is dipstick negative and free of red cells on microscopy may be caused by ingestion of beets, red berries, or food coloring; by urate crystals; or by drugs such as phenazopyridine (Pyridium) and rifampin. A finding of red cell or other casts, lipiduria, or significant proteinuria in combination with hematuria suggests intrinsic renal disease. Microscopic hematuria usually does not produce a positive dipstick test result for protein, but gross hematuria may contribute enough protein to cause a positive result; thus a finding of proteinuria should be confirmed and the amount quantified with a 24-hour urine collection. Hematuria in combination with pyuria or bacteriuria suggests UTI; the infection should be treated and hematuria reassessed after therapy has been completed. Even if white cells or organisms are not seen on urinalysis, the urine should be cultured to rule out hemorrhagic cystitis, especially when lower tract symptoms are present.

Blood studies should be ordered only as necessary to gauge renal function and to confirm causes suggested by the clinical presentation. In the ED setting, routine ordering of the full gamut of chemical and serologic studies necessary to rule out all possible causes of hematuria is rarely appropriate. In particular, a platelet count and coagulation studies are extremely unlikely to be helpful in the absence of a suggestive history or other specific clinical clues.

Radiography and Ultrasonography

The role of urinary tract imaging studies in the immediate evaluation of hematuria also is limited. Visualization of the urinary tract generally is helpful only when the history suggests renal colic or other disorders of the upper urinary tract (e.g., polycystic kidney disease, tumor, obstruction). CT without contrast is the imaging modality of choice.[7] Ultrasonography can be used to determine kidney size and shape and to detect renal masses or obstruction. Further imaging studies, if indicated, should be planned after urologic consultation.

If no upper tract lesions are identified on initial imaging studies, cystoscopy usually is the next step in evaluation because it is the most effective means of visualizing the bladder and the male urethra. It is the initial study of choice for patients with active gross hematuria not caused by an obvious source (e.g., hemorrhagic cystitis); in fact, some urologists prefer to perform endoscopic procedures promptly during an acute bleeding episode to maximize the chance of localizing the source. In older patients in whom urinalysis shows only hematuria and the findings on the history and physical examination are otherwise unhelpful, urinary cytologic examination also may be undertaken.

Monitoring on an outpatient basis constitutes appropriate management in patients with hematuria who have no other abnormality revealed by urinalysis; who are otherwise asymptomatic; who are not azotemic, hypertensive, or severely anemic; and who have no evidence of intrinsic renal disease. (A possible exception may be the patient who has a known bleeding disorder or who is taking an anticoagulant.) Extensive outpatient evaluation for an isolated episode of hematuria usually is not undertaken in patients younger than 40 years unless hematuria is persistent, but it is generally recommended that most patients older than 40 undergo a thorough evaluation after even a single episode of hematuria.

The cause of hematuria can be determined on initial medical and urologic evaluation in about 70% of cases. In other cases a diagnosis of small calculi, occult bladder tumor, arteriovenous malformation, or early glomerulonephritis is made only after repeated examination or the development of further signs or symptoms. In about 20% of cases no cause can be determined.

Proteinuria

Principles of Disease

Abnormal proteinuria is defined as excretion of more than 150 mg of protein (albumin) per 24 hours in adults, or more than 140 $mg/m^2/24$ hr in children. Patients with mild to moderate degrees of proteinuria commonly are identified incidentally on routine urinalysis; patients with more severe degrees of proteinuria often seek medical attention because of edema or other effects of hypoproteinemia.

With alteration in the glomerular capillary barrier (e.g., with the nephrotic syndrome and the many varieties of primary and secondary glomerulonephritis), albumin and globulins, which under normal circumstances are restricted from the glomerular ultrafiltrate because of their ionic charge and size, are lost into the urine. Persistent proteinuria is a marker for renal disease even in the absence of azotemia or an abnormal urine sediment.

Excretion of more than 2 g of protein in 24 hours is likely to be caused by a glomerular process. In the nephrotic syndrome, protein losses exceed the liver's capacity to synthesize albumin, resulting in hypoalbuminemia. This leads to decreased plasma oncotic pressure and accumulation of edema fluid in the extravascular interstitial space. Increased aldosterone secretion and further retention of salt and water ensue. Thus edema is the clinical hallmark of the nephrotic syndrome and often is the initial complaint of patients who have significant proteinuria. Edema ranges in severity from mild dependent peripheral edema or periorbital swelling to frank anasarca with pleural effusions and ascites. *Nephrotic-range proteinuria* is defined arbitrarily as excretion of more than 3.5 g of protein per 24 hours.

Patients with the nephrotic syndrome are at increased risk for thromboembolic events, including deep vein thrombosis of the lower extremity, renal vein thrombosis, and pulmonary embolism. The reason for this propensity appears to be a hypercoagulable state that is complex and incompletely understood.[8] Hyperlipidemia is another typical feature of the nephrotic syndrome; the

mechanism is thought to be related indirectly to hypoalbuminemia and decreased oncotic pressure or viscosity. The major clinical significance of the nephrotic syndrome, however, is that it indicates the presence of an underlying renal process or systemic disease affecting the glomerulus (Box 97-3).

Clinical Features

Evaluation of the patient with proteinuria focuses not only on gauging the severity of proteinuria and the likelihood of complications but also on identifying any associated signs of underlying renal disease or systemic illness. Careful questioning will elicit a history of recent infections or use of medications or drugs or a past history of proteinuria, hypertension, edema, or renal disease. In young female patients, the presence of pregnancy is determined, as pregnancy can exacerbate previously inapparent renal disease; in late pregnancy, proteinuria may be the first sign of preeclampsia. Clues to the presence of systemic diseases that commonly affect the kidneys (e.g., diabetes, collagen vascular disease) should be sought as well. The physical examination includes evaluation of the blood pressure, determination of the presence or absence of edema, and assessment for signs of systemic disease or renal insufficiency.

Laboratory Findings

The laboratory evaluation in the patient with proteinuria includes urinalysis and measurement of the BUN and serum creatinine. Although the finding of isolated proteinuria may or may not be clinically important, proteinuria is almost always significant when it occurs in combination with hematuria. RBCs and red cell casts suggest glomerulonephritis; proteinuria with pyuria may be seen with AIN. The combination of proteinuria and glycosuria suggests diabetic nephropathy. A 24-hour urine collection provides an accurate measure of GFR and will quantify protein excretion.

Abnormal findings on the history, physical examination, or laboratory evaluation greatly increase the probability of the presence of significant renal disease, and early referral to an internist or nephrologist is indicated. However, in the absence of edema, azotemia, hypertension, active urine sediment, or known systemic illness affecting the kidney, patients with proteinuria may be referred to their primary care provider for follow-up. Because transient, mild proteinuria is not uncommon in healthy persons, patients with mild proteinuria as indicated by dipstick testing (particularly if the urine is concentrated) should have dipstick testing repeated at the follow-up visit before further evaluation is undertaken. Persistent proteinuria may necessitate referral to a nephrologist; in some cases, renal biopsy will be necessary to establish a diagnosis and guide management.

ACUTE KIDNEY INJURY

The hallmark of AKI (formerly known as *acute renal failure* [ARF]) is progressive azotemia, which commonly is accompanied by a wide range of other disturbances, depending on the severity and duration of renal dysfunction. These include metabolic derangements (e.g., metabolic acidosis and hyperkalemia), disturbances of body fluid balance (particularly volume overload), and a variety of effects on almost every organ system (Box 97-4).

The causes of AKI may be divided into those that decrease renal blood flow (prerenal), produce a renal parenchymal insult (intrarenal), or obstruct urine flow (obstructive or postrenal). Identification of either a prerenal or a postrenal cause of AKI generally makes it possible to initiate specific corrective therapy; if these two broad categories of AKI can be excluded, an intrarenal cause is implicated. The renal parenchymal causes of AKI can be usefully subdivided into those primarily affecting the glomeruli, the intrarenal vasculature, or the renal interstitium. The term *acute tubular necrosis* denotes another broad category of intrinsic renal failure that cannot be attributed to specific glomerular, vascular, or interstitial causes (Fig. 97-2).[4]

Principles of Disease

Prerenal Azotemia

Decreased renal perfusion that is sufficient to cause a decrease in the GFR results in azotemia. The possible causes can be grouped

into entities causing intravascular volume depletion, volume redistribution, or decreased cardiac output (Box 97-5). Patients who have preexisting renal disease are particularly sensitive to the effects of diminished renal perfusion.

Prerenal azotemia is characterized by increased urine specific gravity, BUN/creatinine ratio generally between 10 : 1 and 20 : 1, urine sodium concentration less than 20 mEq/dL, and FENa less than 1%. The condition generally can be corrected readily by expanding extracellular fluid volume, augmenting cardiac output, or discontinuing vasodilating antihypertensive drugs. However, severe prolonged prerenal azotemia can eventuate in ATN.

Patients who have congestive heart failure (CHF) or cirrhosis form an important subset of those with prerenal azotemia. These patients often are salt-overloaded and water-overloaded, yet their effective intra-arterial volume is decreased. Administration of diuretics has the potential to decrease intravascular volume further, resulting in decreased glomerular filtration and prerenal azotemia. For some patients with advanced CHF or hepatic disease, a state of chronic stable prerenal azotemia may be the best

achievable compromise between symptomatic volume overload and severe renal hypoperfusion.[9]

Glomerular perfusion also may be decreased in patients with normal intravascular volume and normal renal blood flow who take angiotensin-converting enzyme (ACE) inhibitors or, more commonly, prostaglandin inhibitors. All nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, inhibit prostaglandin synthesis. Renal vasodilator prostaglandins are critical in maintaining glomerular perfusion in patients with conditions such as CHF, chronic renal insufficiency, and cirrhosis, in which elevated circulating levels of renin and angiotensin II decrease renal blood flow and GFR. In this setting, a decrease in the production of vasodilator prostaglandins may result in acute intrarenal hemodynamic changes and a reversible decrease in renal function.[10] This phenomenon also is seen with the selective cyclooxygenase-2 inhibitor class of NSAIDs.[11,12] Other risk factors include advanced age, diuretic use, renovascular disease, and diabetes. This entity is distinct from other renal complications of NSAIDs, including interstitial nephritis and papillary necrosis.

Renal insufficiency secondary to NSAIDs generally is reversible after withdrawal of the causative agent. For patients who are at increased risk but require treatment with NSAIDs, a short-acting preparation (e.g., ibuprofen) should be prescribed, and follow-up monitoring of renal function and serum potassium level should begin within days rather than weeks. If renal function is unchanged after a short course of treatment, adverse effects from continuing therapy are unlikely, although other potential mechanisms for the development of renal dysfunction (e.g., interstitial nephritis) should be kept in mind.

Postrenal (Obstructive) Acute Renal Failure

Obstruction is an eminently reversible cause of AKI and should be considered in every patient with newly discovered azotemia or worsening renal function. Obstruction may occur at any level of the urinary tract but most commonly is produced by prostatic hypertrophy or by functional bladder neck obstruction (e.g., secondary to medication side effects or neurogenic bladder) (Box 97-6). Intrarenal obstruction may result from intratubular precipitation of uric acid crystals (e.g., with tumor lysis), oxalic acid (as in ethylene glycol ingestion), phosphates, myeloma proteins, methotrexate, sulfadiazine, acyclovir, or indinavir.[13] Bilateral ureteral obstruction (or obstruction of the ureter of a solitary kidney) may be caused by retroperitoneal fibrosis, tumor, surgical misadventure, stones, or blood clots. A sudden deterioration in renal function in the setting of diabetes mellitus, analgesic nephropathy, or sickle cell disease should suggest papillary necrosis.

Treatment of postrenal AKI consists of relief of the obstruction. In the absence of infection, full renal recovery is possible even after 1 to 2 weeks of total obstruction, although the serum creatinine level may not return to baseline for several weeks. Because the

www.ketabpezeshki.com 66485457-66963820

onset of irreversible loss of renal function with obstruction appears to be gradual, a few days' delay in diagnosis generally is considered acceptable. Still, common sense dictates that obstructions should be detected and relieved promptly.

Intrinsic Acute Renal Failure

Of the specific intrarenal disorders that cause AKI, glomerulonephritis, interstitial nephritis, and abnormalities of the intrarenal vasculature are amenable to specific therapy and are important to consider as possible causes. These entities are responsible for only 5 to 10% of cases of AKI in adult inpatients; most are caused by ATN. In adults in whom AKI develops outside the hospital, the incidence of glomerular, interstitial, and small-vessel disease is much greater. In children, these entities account for approximately one half of the cases of AKI (Box 97-7).[4]

Glomerular Disease. Acute glomerulonephritis may represent a primary renal process or may be the manifestation of any of a wide range of other disease entities (see Box 97-7). Patients may have dark urine, hypertension, edema, or CHF (secondary to volume overload) or may be completely asymptomatic, in which case the diagnosis rests on an incidental finding on urinalysis. The hematuria associated with glomerular disease may be microscopic or gross and may be persistent or intermittent. Proteinuria, although often in the range of 500 mg/day to 3 g/day, not uncommonly is in the nephrotic range. The presence of hematuria, proteinuria, or red cell casts is highly suggestive of glomerulonephritis. In fact, red cell casts are essentially diagnostic of active glomerular disease, although occasionally they are seen with other types of renal disease. Conversely, the absence of red cell casts, proteinuria, and hematuria essentially excludes glomerulonephritis as the cause of AKI.

The specific diagnosis of acute glomerulonephritis caused by primary renal disease often is ultimately made by renal biopsy. However, when glomerulonephritis is secondary to a systemic disease such as systemic lupus erythematosus, the patient's clinical signs and symptoms, in combination with the results of laboratory assessment, aid considerably in narrowing the scope of the differential diagnosis. As a rule, extensive laboratory testing to identify the cause of acute glomerulonephritis is not indicated in the ED setting and is more appropriately performed as part of an inpatient evaluation.

Interstitial Disease. AIN most commonly is precipitated by drug exposure or by infection.[14] Drug-induced AIN is poorly understood, but the absence of a clear relationship to the dose and the recurrence of the syndrome on rechallenge with the offending agent suggests that an immunologic mechanism is responsible. The most commonly incriminated drugs are the penicillins, diuretics, and NSAIDs. AIN has been reported in association with bacterial, fungal, protozoan, and rickettsial infections.

Patients with AIN classically have rash, fever, eosinophilia, and eosinophiluria, but it is common for one or more of these cardinal signs to be absent.[15] Pyuria, gross or microscopic hematuria, and mild proteinuria are observed in some cases. A definite diagnosis sometimes can be made only on renal biopsy. Treatment of AIN is directed at removing the presumed cause; infections should be treated and offending drugs discontinued. Renal function generally returns to baseline over several weeks, although chronic renal failure has been reported to occur.

Intrarenal Vascular Disease. Vascular disease of the kidney can be classified according to the size of the vessel that is affected. Disorders such as renal arterial thrombosis or embolism, which affect large blood vessels, must be bilateral (or affect a single functioning kidney) to produce AKI. Whether to attribute such cases of AKI to prerenal or intrarenal vascular causes is a matter of semantics. The most common cause of thrombosis probably is trauma; thrombosis also may occur after angiography or may be secondary to aortic or renal arterial dissection. Renal atheroembolism is thought to occur commonly—at least on a microscopic level—after arteriography but is an uncommon cause of AKI. Similarly, patients with chronic atrial fibrillation or infective endocarditis may experience embolization of the kidney but rarely develop AKI as a result. Renal arterial embolism can cause acute renal infarction, generally manifested by sudden flank, back, chest, or upper abdominal pain. Urinary findings, including hematuria, are variable. Fever, nausea, and vomiting are not uncommon; in some cases, evidence of embolization to other vessels provides a useful clue. The diagnosis usually is made by renal flow scanning or arteriography. Surgical embolectomy has been reported to restore function when undertaken within several hours of occlusion, but significant return of function has been documented in patients operated on as long as 6 weeks after total occlusion. This outcome presumably is possible because collateral circulation has developed in association with a preexisting partial occlusion.

An interesting but relatively uncommon type of AKI occurs when an ACE inhibitor is given to a patient with underlying bilateral renal artery stenosis (or unilateral stenosis of a solitary functioning kidney). With inhibition of angiotensin synthesis, efferent arteriolar tone is not maintained and GFR decreases. The condition is reversible with cessation of therapy.

Several diseases that affect the smaller intrarenal vessels can cause AKI (see Box 97-7). Patients whose disease is severe enough to cause ARF also generally are found to have hypertension, microangiopathic hemolytic anemia, and other systemic and organ-specific manifestations. Infection with *Escherichia coli* O157:H7 has emerged as a major cause of hemolytic uremic syndrome, an important cause of AKI in children.[16]

Malignant hypertension, although much less common since the advent of more effective antihypertensive therapy, has by no means disappeared. Patients with scleroderma (systemic sclerosis) may have "scleroderma renal crisis,"[17,18] characterized by malignant hypertension and rapidly progressive renal failure. Whereas vasculitis associated with glomerular capillary inflammation typically causes gross or microscopic hematuria and formation of red cell casts, vascular involvement of the medium-size vessels, such as that produced by scleroderma, often spares the preglomerular vessels and tends not to produce an active urine sediment. Extrarenal manifestations (rash, fever, arthritis, pulmonary symptoms) are usually evident.

For malignant hypertension, both as a separate entity and as a part of scleroderma renal crisis, appropriate treatment can produce a gratifying remission of AKI. Patients with malignant hypertension have been reported to recover renal function after aggressive antihypertensive therapy, with temporary maintenance with dialysis if necessary.[19] In patients with scleroderma renal crisis, specific therapy with ACE inhibitors has been shown to result in improvement in renal function in a significant proportion of cases.[18]

Acute Tubular Necrosis

The term *acute tubular necrosis* refers to a generally reversible deterioration of kidney function associated with a variety of renal insults. Oliguria may or may not be a feature. The diagnosis is made after prerenal and postrenal causes of ARF and disorders of glomeruli, interstitium, and intrarenal vasculature have been excluded. These discrete categories do overlap in a few disorders. For example, AKI associated with multiple myeloma or ethylene glycol toxicity is associated with both intrarenal obstruction and interstitial disease, as well as a probable direct toxic effect on the renal tubule itself.

The most common precipitant of ATN is renal ischemia occurring during surgery or after trauma and sepsis.[20] The remainder of cases occur in the setting of medical illness, most commonly as a result of the administration of nephrotoxic aminoglycoside antibiotics or radiocontrast agents or in association with rhabdomyolysis. Multiple causes can be identified in some cases; in others a definitive cause is never established.

Decreased renal perfusion results in a continuum of renal dysfunction that ranges from transient prerenal azotemia at one extreme to ATN at the other. Early during the period of renal ischemia, renal function can be restored completely by restoring renal blood flow, but at some point, continued hypoperfusion results in renal dysfunction unresponsive to volume repletion, and ATN will supervene. ATN may occur in the absence of frank hypotension; even modest renal ischemia may result in ATN in susceptible persons. Individual susceptibility to ATN may be related to the balance of prostaglandin-mediated vasopressor and vasodilatory influences on the renal vasculature.

Postischemic ATN can occur in the setting of volume loss from the GI tract (upper or lower), skin, or kidneys or can result from severe hemorrhage or major burns. Heatstroke commonly is associated with the development of ATN, which is thought to result from a combination of volume loss, hyperpyrexia, and rhabdomyolysis. Another cause of ATN is hyperglycemic hyperosmolar nonketotic coma, which can be associated with loss of as much as 25% of total body water. ATN also is seen in the setting of cardiogenic shock, sepsis, and third spacing of fluids in pancreatitis and peritonitis.

ATN is common in postoperative patients, although not all cases can be attributed to intraoperative hypotension or hemorrhage. Concomitant sepsis, increased age, preexisting renal disease, and other comorbid conditions are associated with a worse outcome.[20,21]

Box 97-8 Causes of Pigment-Induced Acute Kidney Injury

Myopathy	G6PD deficiency

G6PD, glucose-6-phosphate dehydrogenase; *RBCs,* red blood cells.

Nephrotoxins constitute the other major cause of ATN. Among the most prominent of these are the endogenous pigments myoglobin and hemoglobin. Rhabdomyolysis and ARF resulting from crush injuries first received widespread attention after their description in survivors of the London blitz during World War II, but many other causes of pigment nephropathy have been reported (Box 97-8). Hypotension secondary to fluid loss into damaged muscle is thought to worsen the effects of myoglobinuria on the renal tubule, as does acidemia. Hemolysis, resulting in the release of hemoglobin into the circulation and hemoglobinuria, can cause ATN but usually only in the presence of coexisting dehydration, acidosis, or other causes of decreased renal perfusion. ATN may be associated with the hemolysis of as little as 100 mL of blood.

ATN associated with rhabdomyolysis is often oliguric; it is characterized by rapid increases in the serum creatinine, potassium, phosphorus, and uric acid levels.[22,23] Creatine released from muscle is metabolized to creatinine, which may result in serum creatinine increases of more than 2 mg/dL/day, in contrast to the increase of 0.5 to 1.0 mg/dL/day typically seen in other forms of AKI. The BUN/creatinine ratio often is less than 10 : 1. Intracellular potassium released from damaged muscle may raise the serum potassium by 1 to 2 mEq/L in several hours. Likewise, phosphate released from muscle may cause dramatic increases in the serum phosphate level. Uric acid, produced by metabolism of purines released from damaged muscle, may accumulate to levels high enough to cause acute uric acid nephropathy.

Urine dipstick testing yields a positive result for heme in only 50% of patients with rhabdomyolysis, because myoglobin is rapidly cleared from the serum and may therefore be undetectable in the urine at the time of presentation. Thus a negative result on urine dipstick testing does not rule out the diagnosis. Serum creatine kinase (CK) is cleared much more slowly, so measurement of serum CK levels is a more sensitive test.

No biochemical parameter can be used to predict which patients who have rhabdomyolysis will experience AKI. In one classic study of patients in whom alcoholism, muscle compression, and seizures were the most common causes of rhabdomyolysis, AKI developed in only one third.[22] Neither the degree of serum CK elevation, the presence (or absence) of myoglobinuria, nor the degree of hyperkalemia correlates well with the development of AKI.

Antibiotics and radiographic contrast agents are other nephrotoxins that commonly are implicated in the development of ATN. Aminoglycosides are the most commonly implicated antibiotics. Higher doses and longer duration of therapy are associated with higher serum drug levels, leading to greater accumulation of drug in the renal parenchyma and a greater likelihood of nephrotoxicity. Increased age, impaired renal function, dehydration, and exposure to other nephrotoxins are additional risk factors. Once-daily administration of a somewhat higher dose is associated with less nephrotoxicity but equal effectiveness.[24,25]

www.ketabpezeshki.com 66485457-66963820

Aminoglycoside-induced ATN typically has a gradual onset. Clinically significant renal dysfunction usually occurs only after several days and often after more than a week of therapy. However, renal failure can develop as late as 10 days after a drug has been discontinued, an observation that appears to be explained by the prolonged tissue half-life characteristic of these agents. Renal function returns to normal after an average of 6 weeks, but the condition occasionally progresses to permanent renal injury.

Radiographic contrast agents constitute a common cause of hospital-acquired renal insufficiency. Renal failure produced by these agents has been defined as an increase in serum creatinine level of 25% over baseline with a temporal relation to contrast medium administration and in the absence of other identifiable causes. Radiocontrast agent–induced ATN encompasses a spectrum ranging from asymptomatic nonoliguric renal insufficiency to severe renal failure requiring dialysis, but most cases are mild. It can occur after any procedure involving intravascular administration of contrast material. Typically, an increase in the serum creatinine level is noted within 3 days of exposure, with a return to normal within 10 to 14 days.

The most important risk factors for radiocontrast agent–induced ATN are preexisting renal insufficiency, diabetes mellitus, multiple myeloma, age older than 60 years, volume depletion, and higher doses of contrast material. Among these, preexisting renal insufficiency is the most important.[26] Diabetic patients with a serum creatinine level less than 1.5 mg/dL are at low risk for the development of radiocontrast agent–induced ATN, whereas those whose serum creatinine is greater than 1.5 mg/dL are at significant risk. Multiple myeloma, particularly in patients who are dehydrated, is another reasonably well-documented risk factor. Advanced age also appears to make ATN more likely, possibly because of decreased renal mass and cortical blood flow. Volume depletion appears to be an independent risk factor, and aggressive volume expansion before contrast exposure has been shown to have a protective effect.[27,28] Finally, large doses and repeated doses of contrast material are associated with increased risk of ATN, particularly if a second study is performed within 72 hours of the first.

N-acetylcysteine in combination with periprocedural hydration appears to decrease the incidence of contrast-associated ATN,[29] although this has not been a consistent finding in published studies.[30] Modest volumes of intravenous normal saline (3 mL/kg over 1 hour, followed by 1.5 mL/kg/hr for 4 hours after contrast exposure) appear to be effective in decreasing the likelihood of nephrotoxicity; sodium bicarbonate does not appear to offer an advantage over normal saline.[30,31] Recent reviews continue to emphasize the importance of appropriately limiting exposure to contrast agents as well as ensuring preprocedural hydration.[27]

Clinical Features

When the presence of azotemia or renal failure has been discovered, the first consideration in the ED evaluation should be the possibility of potentially life-threatening complications (e.g., hyperkalemia, pulmonary edema). Assuming these have been satisfactorily ruled out, the next step is to determine whether the condition represents AKI or is the result of preexisting renal disease. The clinical distinction between AKI and chronic kidney disease (CKD) often is difficult; old records and laboratory results are invaluable. The finding of small kidneys on abdominal radiography or bone changes of secondary hyperparathyroidism on hand films suggests that the renal failure is chronic. Anemia, hypocalcemia, and hyperphosphatemia, on the other hand, should not be relied on to identify patients who have CKD because these abnormalities can develop rapidly in AKI.

In evaluating the patient with azotemia, the clinician uses history, physical examination, and laboratory studies to seek clues to the cause and to identify signs and symptoms of uremia, volume overload, or other complications of renal failure. In attempting to identify the cause of azotemia, the general strategy is to rule out both prerenal and postrenal causes before considering the many intrinsic renal causes. First, potential sources of volume loss and causes of decreased cardiac output are sought in the history, and the patient is questioned about lightheadedness, bleeding, GI fluid loss, abnormal polyuria, or symptoms of CHF. In men a history of nocturia, frequency, hesitancy, or decreased urinary stream suggests prostatic obstruction. A history of lower tract symptoms or of abdominal or pelvic tumor in either sex is determined, as is a history of kidney stones or chronic UTI. A history of acute anuria (defined as the production of less than 100 mL of urine per day) is most often the result of high-grade urinary tract obstruction, although it also may accompany severe volume depletion, severe acute glomerulonephritis, cortical necrosis, or bilateral renal vascular occlusion. Intermittent anuria, on the other hand, is characteristic of obstructive disease.

Medication use and possible exposure to radiographic contrast agents or other exogenous toxins are other key components of the history. A history of hypertension, dark-colored urine, rash, fever, or arthritis suggests intrinsic renal disease or a multisystem disorder. In older patients the presence of symptoms suggestive of multiple myeloma should be elicited.

The physical examination focuses on signs of volume depletion such as tachycardia and decreased skin turgor. Documented short-term changes in body weight offer a valuable clue in assessing volume status, particularly in chronically ill patients. In addition, suspected bleeding should be specifically excluded. Similarly, volume overload is determined by assessment of jugular vein distention and attention to the presence of rales, an S_3 gallop, or edema.

The area of the bladder is palpated and percussed. A distended bladder is percussible when it contains 150 mL of urine, and the dome is palpable abdominally when it contains 500 mL. Ultrasonography can be used to detect bladder distention or postvoid residual volume if there is a question of urinary retention.[32]

Prostate examination in adult men and pelvic examination in adult women are necessary components of the examination. The presence of rash, purpura, pallor, or petechiae is noted, as is arthritis, musculoskeletal tenderness, or findings suggestive of infection or malignancy.

Diagnostic Strategy

Laboratory Findings

The laboratory evaluation begins with a dipstick and microscopic urinalysis and measurement of urine output. BUN, serum creatinine, urine sodium, and FENa levels are determined to help evaluate renal function and to provide clues to the cause of AKI. A complete blood count, serum electrolyte panel (expanded to include calcium, phosphorus, and magnesium determinations), electrocardiogram (ECG), and chest radiograph help to establish the patient's baseline status and to provide information about possible complications. Other studies may be of value in the ED setting when the history or physical findings suggest that they may have a specific role in immediate diagnosis or management.

Prerenal azotemia is suspected in the setting of volume loss, volume redistribution, or decreased effective renal perfusion. It typically is associated with a normal urinalysis, high BUN/creatinine ratio, increased urine osmolality, a urine sodium concentration less than 20 mEq/L, and FENa less than 1%. A rapid response to volume repletion also is characteristic.

Urethral or bladder neck obstruction is documented by the finding of significant amounts of residual urine in the bladder (by catheterization or ultrasound examination) after the patient has

www.ketabpezeshki.com 66485457-66963820

voided or attempted to void spontaneously. An important point is that the ability to void does not rule out obstruction. In fact, the urine volume in the presence of obstruction may range from zero to several liters per day. Flank pain is likewise an insensitive marker for obstruction. Urine indices and the BUN/creatinine ratio tend not to be helpful, although an increase in the latter is common in obstruction. A renal parenchymal disorder often can be diagnosed by its manifestations on microscopic urinalysis or by associated extrarenal manifestations (e.g., with multisystem disease) or the clinical setting (e.g., recent exposure to a new medication). The absence of evidence of prerenal or postrenal causes in a patient with AKI may be taken as presumptive evidence of an intrarenal parenchymal process. Among these, the possibility of an acute or ongoing vascular insult should be kept in mind, because timely intervention may be important in preserving ultimate renal function.

Radiography and Ultrasonography

Significant hydronephrosis usually is readily demonstrable by ultrasonography and may indicate either upper or lower tract obstruction. In questionable cases, or if bilateral ureteral obstruction is strongly suspected on the basis of clinical findings, the next step is retrograde urography performed by a urologist.[33] CT imaging is less useful in this setting; in fact, intravenous radiocontrast material may compound the injury to the kidney.

Management

ED management of AKI is directed at reversing decreases in GFR and urine output (if possible) while minimizing further hemodynamic and toxic insults, maintaining normal fluid and electrolyte balance, and managing other complications of AKI as required. Because renal failure alters the metabolism and action of many drugs, often in ways that are not predictable, great care should be exercised in prescribing all medications. A compendium of guidelines for drug dosage in renal failure, such as the one by Aronoff and colleagues,[34] is of great help for this purpose.

After ensuring that the vital signs are adequate and that the patient is in no immediate danger from volume or metabolic derangements, the next step is to correct prerenal and postrenal factors, if any are identified. Intravascular volume is repleted in hypovolemic patients and maintained in euvolemic patients by matching input to measured and insensible output. Inadequate cardiac output is augmented when possible. Postrenal or obstructive ARF is treated by restoration of normal urine outflow. Bladder outlet obstruction may be relieved by passage of a Foley catheter, whereas upper tract obstruction may require percutaneous nephrostomy.

When prerenal and postrenal factors have been ruled out, the challenge to the emergency physician is to identify the cause of intrinsic renal AKI, keeping in mind the multitude of known possible causes (see Box 97-7). The clinical setting and physical and laboratory findings often allow the scope of the differential diagnosis to be considerably narrowed. The clinical picture is often most consistent with the broad category of ATN.

It has been noted repeatedly that patients who have oliguric AKI have a significantly higher mortality rate and a much greater risk of complications than those who are not oliguric. The difference in prognosis may simply reflect a more severe renal insult in patients who are oliguric, however, and it is not clear that interventions aimed at converting oliguric to nonoliguric AKI have an effect on renal function or mortality.[20] Nevertheless, because nonoliguric patients are easier to manage, an attempt to increase urine flow is warranted.

Use of loop diuretics or mannitol often is effective in increasing urine flow when intravascular volume deficits have been corrected. Furosemide has not been shown to shorten the clinical course or affect mortality. Mannitol appears to be most useful when given at the time of or shortly after the renal insult; the recommended dose is 12.5 to 25 g given intravenously (IV). If urine output does not increase, further doses may cause hyperosmolality and clinically significant intravascular volume overload in patients with impaired renal function.[35]

Dopamine also has been used, with and without furosemide, in an effort to increase urine output, but has not proven effective.

Certain specific considerations apply to toxin-induced ATN. Pigment-induced ATN may be prevented by avoidance of hemolysis and muscle injury and by correction of the factors (e.g., dehydration, acidemia) that are known to predispose patients with pigmenturia to the development of renal failure. When hemolysis or rhabdomyolysis has occurred, treatment is directed at eliminating the cause and preventing the development of renal failure.

Mannitol has been shown to prevent AKI in experimental models of myoglobinuria, presumably by inducing osmotic diuresis and decreasing intratubular deposition of pigment. Furosemide, on the other hand, has not consistently shown a beneficial effect. Other studies have suggested that myoglobin precipitates in an acid urine but not in an alkaline urine. Thus, aggressive volume repletion, alkalinization, and mannitol infusion have traditionally been recommended after crush injuries to reduce the likelihood or severity of AKI.[23] This regimen also helps control hyperkalemia. Other evidence, however, suggests that aggressive volume resuscitation alone may be equally effective.[23] When AKI has occurred, management is similar to that of other forms of AKI, but early dialysis may be required to control rapidly developing hyperkalemia, hyperphosphatemia, and hyperuricemia.

Patients who have radiocontrast agent–induced ATN usually require only supportive therapy but are often hospitalized and seen by a nephrologist. A more significant aspect of ED management is *preventing* the occurrence of contrast nephropathy, particularly by identification of risk factors in patients for whom contrast studies are being considered. BUN and serum creatinine levels should be checked before contrast exposure in patients with risk factors. Moreover, before contrast medium is administered to a high-risk patient, it should be established that there is a compelling reason to perform the contrast study and that there is no adequate alternative to use of a contrast agent. The patient should be volume repleted before the study, the administered dose of contrast agent should be kept as low as possible, and multiple studies should be avoided, as should concomitant use of other nephrotoxins. As noted previously, *N*-acetylcysteine given before and after contrast administration appears to decrease the incidence of contrast nephropathy. Intravenous saline given before and after contrast administration appears to be at least as important in prevention.[27-31]

Volume and Metabolic Complications

In addition to those general measures aimed at minimizing decreases in GFR and increasing urine output, an important component of the management of AKI is the prevention or control of systemic complications. Of particular significance in this regard are metabolic derangements (e.g., hyperkalemia, hypocalcemia, hyperphosphatemia, metabolic acidosis) and complications of volume overload (e.g., hypertension, CHF).

Hyperkalemia, the most common metabolic cause of death in patients with AKI, results from an inability to excrete endogenous and exogenous potassium loads. In oliguric patients the serum potassium level typically increases by 0.3 to 0.5 mEq/L per day, but greater increases occur in catabolic, septic, or traumatized patients and in the presence of acidosis or exogenous potassium loads from diet or medication.

www.ketabpezeshki.com 66485457-66963820

Hyperkalemia results in serious disturbances in cardiac electrophysiology that may culminate in cardiac arrest. Although some hyperkalemic patients note muscular weakness, most generally are asymptomatic until major manifestations of cardiotoxicity appear. Accordingly, detection of hyperkalemia is a primary consideration in these patients. ECG changes correlate only roughly with the serum potassium level. Mild hyperkalemia (serum potassium less than 6.0 mEq/L) may be cautiously observed without specific treatment while all exogenous sources of potassium are eliminated. If the serum potassium level is greater than 6.5 mEq/L, and particularly if ECG changes are present, urgent intervention is necessary. When cardiotoxicity must be reversed immediately (e.g., when there is hemodynamic compromise), intravenous calcium (10 mL of 10% calcium gluconate or calcium chloride infused over 2 minutes and repeated after 5 minutes if necessary) is the treatment of choice. Calcium directly antagonizes the membrane effects of hyperkalemia. Intravenous insulin (given with glucose to prevent hypoglycemia) temporarily shifts potassium to the intracellular space. Bicarbonate appears to be less effective in shifting potassium into cells than once thought.[36] It should be used with caution in patients with renal failure because of its potential to cause volume overload and to provoke hypocalcemic tetany or seizures. The safety and efficacy of beta-agonists in hyperkalemic patients have been well documented; like insulin, inhaled albuterol (in a dose of 10-20 mg) causes potassium to move into cells, thereby controlling hyperkalemia for 2 hours or more.[37,38] Elimination of potassium from the body can be promoted by use of a potassium-binding ion exchange resin (sodium polystyrene sulfonate [Kayexalate]) or, much more effectively, by enhancing urinary potassium excretion or by initiating dialysis.[36] Hypocalcemia is a common feature of AKI and can develop rapidly after its onset. Vitamin D–dependent intestinal absorption of calcium is decreased in AKI because of decreased renal synthesis of 1,25-dihydroxyvitamin D. Another factor promoting hypocalcemia is the complexing of calcium with retained phosphate. Rhabdomyolysis-associated AKI in particular often is associated with the deposition of complexed calcium in muscle and other tissues. Asymptomatic hypocalcemia requires no immediate treatment, but subtle or frank tetany should be treated with intravenous calcium (10-20 mL of 10% calcium gluconate infused over several minutes).

Hyperphosphatemia resulting from decreased renal elimination of phosphate is another common feature of AKI. The serum phosphorus level usually ranges from 6 to 8 mg/dL but may be much higher with rhabdomyolysis or in catabolic states. A calcium-phosphate product greater than 70 may result in metastatic soft tissue calcification. Hyperphosphatemia often is treated with oral calcium-based antacids that bind ingested phosphate in the gut.[39]

Acids produced in normal metabolic processes accumulate in AKI and are buffered in part by serum bicarbonate, resulting in a decrease in the serum bicarbonate level and a high–anion-gap metabolic acidosis. Compensatory hyperventilation may be mistakenly attributed to primary cardiac failure or volume overload. The metabolic acidosis associated with AKI usually is mild, and treatment generally is not necessary if the serum bicarbonate level is greater than 10 mEq/L. Overzealous correction may result in hypokalemia, hypocalcemia, or volume overload.

Hypermagnesemia may complicate AKI when patients are given magnesium-containing antacids or laxatives. Thus these products, as well as magnesium itself (e.g., when given for preeclampsia or for treatment of arrhythmia or wheezing), should be avoided in the setting of AKI.

Disturbances of volume regulation can be expected to occur in most patients with AKI. Some nonoliguric patients excrete enough salt and water that intravascular volume depletion can occur if adequate fluid replacement is not provided. Volume depletion prolongs recovery from AKI. Much more commonly, AKI is complicated by volume overload because sodium and water excretion may be inadequate to match even modest intakes. Volume overload is largely responsible for the hypertension often seen in AKI and commonly leads to CHF and pulmonary edema. Iatrogenic volume overload is particularly common and can be prevented only by careful attention to fluid intake and output with prudent estimates of insensible loss. Volume overload can be treated with diuretics or intravenous nitroglycerin while preparations are being made to initiate dialysis.

Organ System Effects

The clinician should be alert to the numerous other important systemic and organ-specific effects of renal failure. Only the more prominent of these are mentioned here.

Uremia impairs host defenses, particularly leukocyte function, and infection is a significant cause of morbidity and mortality in AKI. Thus patients with fever require prompt investigation and aggressive treatment.

Pericarditis, which has a prevalence of 10 to 20% in dialyzed patients with CKD, also may occur in patients with AKI. Chest pain that is worse in a recumbent position is the most common symptom, and most patients have a pericardial friction rub. Fever is common. The ECG may show ST-T wave elevation, low voltage, electrical alternans, or atrial fibrillation. The presence of pericardial effusion is identified most accurately by echocardiography; tamponade, with typical clinical signs, occurs in some patients. In contrast to the situation in chronic kidney failure, pericarditis or pericardial effusion in the setting of AKI generally is an indication for the urgent initiation of dialysis. Patients who have hemodynamically significant tamponade require surgical drainage of the effusion or, occasionally, emergency pericardiocentesis.

Neurologic abnormalities in AKI may be precipitated by electrolyte abnormalities, medications, or uremia. Common signs and symptoms in uremic patients include lethargy, confusion, agitation, asterixis, myoclonus, and seizures.

Anorexia, nausea, vomiting, gastritis, and pancreatitis also are associated with AKI. Significant GI hemorrhage is seen in about 10% of patients.

Impaired erythropoiesis, shortened RBC survival, hemolysis, hemodilution, and GI blood loss all play a role in the normocytic normochromic anemia that usually accompanies AKI. Although mild thrombocytopenia may be present, it is the qualitative defect in platelet function, which is felt to be caused by the effect of circulating uremic toxins, that is more significant and that contributes to these patients' bleeding tendencies. In patients with active bleeding or those in whom an invasive procedure is being contemplated, the prolonged bleeding time can be corrected pharmacologically.[40] Administration of 1-deamino-8-D-arginine vasopressin (DDAVP) shortens the bleeding time within 30 minutes. Infusion of 10 units of cryoprecipitate normalizes the bleeding time in 1 to 2 hours, with a return to baseline in 24 hours.

Disposition

Patients with new-onset AKI should be hospitalized. If nephrology consultation and dialysis facilities are not available, transfer to another institution is advisable, once volume and metabolic abnormalities have been adequately controlled and the patient is hemodynamically stable.

Decisions regarding dialysis generally are made by the nephrology consultant and take into account many factors, including laboratory test abnormalities and the presence or absence of signs and symptoms of uremia (e.g., nausea, vomiting, change in mental status). Many nephrologists choose to initiate dialysis when the

www.ketabpezeshki.com 66485457-66963820

BUN level exceeds 100 mg/dL or the serum creatinine level exceeds 10 mg/dL. Intractable volume overload and life-threatening hyperkalemia are the two most common indications for emergency dialysis.

CHRONIC KIDNEY DISEASE

In contrast to the typical patient with AKI, the patient with CKD has most commonly experienced a slowly progressive course of decreasing renal function over months or years and is likely to have either slowly progressive symptoms or acute problems brought on by superimposed illness, trauma, or other physiologic stress. The most common problems requiring emergent intervention are severe hyperkalemia and symptomatic volume overload.

Barring renal transplantation, CKD is an essentially irreversible condition generally characterized by a relentless decrease in renal function. Thus, whereas preservation of renal function may be a high priority in the patient with known AKI, management need not as a rule involve efforts to reverse the process presumed to have caused CKD, nor even perhaps efforts to determine the exact cause. On occasion, however, the kidney disease may have a reversible component. In some cases the underlying pathologic process affecting the kidneys may be arrested or treated; more commonly, correctable extrarenal factors (e.g., volume depletion or urinary tract obstruction) may be identified.

In the patient with CKD who has an acute problem, the focus should be the identification and treatment of an intercurrent illness that has caused clinical decompensation, with the goal of returning the patient to a stable, chronically compensated status.

Principles of Disease

The standard terminology for chronic renal failure has changed.[41] *Chronic kidney disease* denotes kidney damage or decreased renal function for 3 months or more and is characterized by irreversible nephron loss and scarring. *Chronic renal insufficiency,* which denotes a condition in which GFR has been moderately reduced but not to a degree sufficient to cause clear-cut clinical symptoms, has been replaced by an indication of the degree to which GFR is reduced. *End-stage renal disease,* now termed *kidney failure,* describes a condition in which renal function has diminished to a low level and in which serious, life-threatening manifestations can be expected to occur without dialysis or transplantation. At this stage the kidneys often are shrunken and diffusely scarred to such a degree that it may be impossible to make an etiologic diagnosis, even on pathologic examination.

The causes of CKD are numerous; their relative frequency depends primarily on the population studied. As with AKI, they can be conveniently classified (Box 97-9) as prerenal (vascular), intrinsic renal (glomerular and tubulointerstitial), or postrenal (obstructive). Glomerular disease accounts for approximately one third to one half of the cases of CKD; in the United States, diabetic nephropathy forms the largest group of these. Hypertensive nephrosclerosis is another important cause, particularly among blacks, in whom it may be the cause of 25% or more of cases of CKD. Among children and adolescents, reflux nephropathy is the most common cause of CKD. Renal failure related to intravenous drug use or to human immunodeficiency virus disease is a major consideration in some populations. Clues to other specific causes may be gained from elements of the history, physical examination, or laboratory and imaging studies. Although determining the underlying cause of CKD can permit the underlying disease to be treated and make possible some improvement in renal function in some cases, this is the exception rather than the rule.

Box 97-9 Major Causes of Chronic Kidney Disease

Vascular Causes
Renal arterial disease
Hypertensive nephrosclerosis

Glomerular Causes
Primary Glomerulopathies
Focal sclerosing glomerulonephritis (GN)
Membranoproliferative GN
Membranous GN
Crescentic GN
IgA nephropathy

Secondary Glomerulopathies
Diabetic nephropathy
Collagen vascular disease
Amyloidosis
Postinfectious
HIV nephropathy

Tubulointerstitial Causes
Nephrotoxins
Analgesic nephropathy
Hypercalcemia or nephrocalcinosis
Multiple myeloma
Reflux nephropathy
Sickle nephropathy
Chronic pyelonephritis
Tuberculosis

Obstructive Causes
Nephrolithiasis
Ureteral tuberculosis
Retroperitoneal fibrosis
Retroperitoneal tumor
Prostatic obstruction
Congenital abnormalities

Hereditary Causes
Polycystic kidney disease
Alport's syndrome
Medullary cystic disease

HIV, human immunodeficiency virus; *IgA,* immunoglobulin A.

Uremia

Progressive loss of renal function eventually results in a recognizable syndrome termed *uremia.* Clinical manifestations do not generally appear, however, until GFR has been reduced to approximately 15 to 20% of normal.

As the patient becomes unable to excrete an ingested salt or water load promptly, external balance of sodium and water is affected; volume overload or hypernatremia or hyponatremia may result. Inability to concentrate the urine is an early manifestation of renal insufficiency and may be manifested as nocturia. Potassium homeostasis is likewise disrupted, and a relatively small potassium load may lead to dangerous hyperkalemia. Acid-base balance is affected, because the kidney fails to clear the daily metabolic acid load owing to a decreased ability to excrete ammonium and phosphate; the result is a non–anion-gap acidosis in the earlier stages of CKD and a superimposed anion-gap acidosis as GFR decreases further. Calcium and phosphate metabolism is affected as well; retention of phosphate and progressive loss of the kidney's capacity to synthesize 1,25-dihydroxycholecalciferol, the active form of vitamin D, lead to hypocalcemia, secondary hyperparathyroidism, and eventually the development of renal osteodystrophy.

Nitrogenous byproducts of protein catabolism retained in the blood are the presumed cause of many of the diverse abnormalities of organ function in renal failure. Most patients with CKD show decreased glucose tolerance, although it is rarely severe enough to require treatment unless the medical history includes established diabetes. In such cases, insulin or other hypoglycemic therapy may need to be continued but generally at a lower dosage than required before the onset of renal failure, because the normal kidney has a major role in insulin degradation. Alterations in lipid metabolism result in elevated low-density lipoproteins and hypertriglyceridemia in many patients with CKD.

Clinical Features

Uremia has specific effects on a variety of organ systems. Many of these manifestations are relieved by dialysis, but others are not. A number have been attributed in some degree to the retention of nitrogenous wastes and to the previously noted derangements in vitamin D and parathyroid hormone metabolism.

www.ketabpezeshki.com 66485457-66963820

Cardiovascular System

The cardiovascular system is perhaps most dramatically affected in CKD.[42-44] Many of the manifestations can be attributed to the effects of chronic volume overload, anemia, hyperlipidemia, alterations in calcium and phosphorus metabolism, and volume- and hormonally mediated hypertension.[44-47] Pericarditis, with or without pericardial fluid accumulation, also is common in CKD, particularly among patients who have not had dialysis.

Pulmonary Effects

Similarly, uremic pleuritis, with or without associated pleural fluid collections, may develop in some patients. So-called "uremic lung," manifested radiographically by "batwing" perihilar infiltrates, represents pulmonary edema and is almost always caused by volume overload or myocardial dysfunction. Noninflammatory pleural effusion caused by volume overload also is fairly common. Of special importance in the ED evaluation is the fact that the radiographic appearance in pulmonary edema may at times be misleading, simulating an infectious lobar infiltrate or even assuming a nodular appearance in some cases.[48]

Neurologic Features

Neurologic dysfunction is common in advanced uremia and usually manifests with lethargy, somnolence, difficulty concentrating, or frank alteration in mental status. Seizures also may occur, although causes other than uremia alone must be ruled out. Uremic encephalopathy also commonly manifests with hiccups, asterixis, or myoclonic twitching. The last should not be confused with tetany caused by hypocalcemia, which also is common in untreated patients with CKD. In the peripheral nervous system, uremia often causes cramps and a distal sensorimotor neuropathy. A troublesome and characteristic complaint is restless legs syndrome, in which persistent neuropathic discomfort in the legs can be relieved only by movement.

Gastrointestinal System

Anorexia, nausea, and vomiting are nearly constant features of uremia. These GI manifestations are thought to be caused by accumulation of nitrogenous wastes because they often are relieved, even in the undialyzed patient, by introduction of a low-protein diet, and seem to correlate roughly with the BUN level.

Dermatologic Features

The skin of patients with CKD has a characteristic yellowish tinge. Uremic frost, the result of deposition of urea from evaporated sweat on the skin, is a classic finding that, like "uremic fetor," is seen only rarely now with the widespread use of dialysis (Fig. 97-3). Diffuse pruritus is often a major source of discomfort for the patient with CKD; in some cases it may be caused by calcium deposition in the skin secondary to derangements in calcium metabolism.

The use of gadolinium-based contrast agents for magnetic resonance imaging (MRI) has been associated with the development of nephrogenic systemic fibrosis, a potentially fatal disorder that occurs in patients with chronic kidney failure.[49]

Musculoskeletal System

The bones and joints are sites of problems for many of these patients, particularly those with long-standing renal disease. The complex disturbances of calcium and phosphate metabolism in CKD result in renal osteodystrophy, a clinical entity encompassing several overlapping varieties of bone disease that can cause bone pain or frank fractures. Patients with CKD generally are treated with long-term oral calcium and vitamin D in an effort to prevent both secondary hyperparathyroidism and uremic osteodystrophy. Occasional patients will have a poor response to therapy and require parathyroidectomy.

A specific type of arthritis caused by deposition of calcium hydroxyapatite or calcium oxalate crystals in joints is seen in some patients, as are periarticular calcium deposition, spontaneous tendon rupture, myopathy, and carpal tunnel syndrome.

Figure 97-3. Uremic frost. Note the fine white powder on the skin of this patient with kidney failure.

Immunologic Considerations

Uremic patients have long been noted to have an increased susceptibility to infection, even when not challenged by the invasive procedures associated with dialysis. Both humoral and cellular immunity have been shown to be affected. The relative importance of each in the pathogenesis of infection in renal failure has not been clarified, but defects in cellular immunity appear to be more significant clinically. Although patients with renal failure should be considered to be immunocompromised, most infections in patients with CKD are caused by common pathogens rather than opportunistic organisms.

Hematologic Effects

A pronounced normochromic normocytic anemia, with a hematocrit commonly in the range of 18 to 25%, is nearly universal in untreated CKD, except among patients with polycystic disease. It is caused primarily by the kidneys' decreased production of erythropoietin, a hormone that stimulates red cell production by the bone marrow. Other contributing factors are increased red cell hemolysis, nutritional deficiencies, and increased bleeding secondary to platelet dysfunction.

Although platelet number generally is normal in uremia, the bleeding time is prolonged because of defective platelet adhesiveness and activation. Numerous ecchymoses, seen in many patients with CKD, is a common manifestation.

Diagnostic Strategies

The patient with CKD, particularly one who is not yet receiving dialysis, is likely to be seen in the ED with one of the

manifestations previously noted. In cases in which the diagnosis of renal failure has not previously been made, patients' complaints most commonly are nonspecific and often of insidious onset, such as generalized weakness, poor appetite, or deterioration of mental functioning. The initial laboratory finding of a reasonably well-tolerated but rather severe anemia may be the first clue to the diagnosis, which is subsequently confirmed by elevated BUN and serum creatinine levels. A prudent next step is to check the ECG for evidence of immediately life-threatening hyperkalemia before further laboratory and radiographic investigations are undertaken.

Once it has been determined that the patient is in no immediate danger, the ED evaluation can establish that renal failure is indeed chronic rather than acute. An explicit history to that effect obtained from previous medical records or from the patient or family provides the most straightforward and reliable confirmation, as does the presence of a dialysis access device on physical examination. If such a history is unavailable, the finding of bilaterally small kidneys (readily detected on plain abdominal films or by ultrasonography) constitutes equally good evidence. However, the converse is not necessarily true—a finding of normal-sized or large kidneys does not rule out CKD (Box 97-10). In such cases, additional diagnostic steps are required to establish the diagnosis. A convincing history of the long-standing presence of the presenting symptoms or of symptoms such as nocturia may be helpful in suggesting chronicity, as may a history of familial kidney disease such as polycystic kidney disease or Alport's syndrome. Laboratory abnormalities such as anemia, acidosis, hyperuricemia, hypocalcemia, and hyperphosphatemia can occur in patients with *acute* kidney failure as early as 10 days after onset. Although urinary findings likewise tend not to be helpful, the presence of broad waxy casts on microscopic examination is suggestive of chronic disease, whereas the finding of an "active" sediment (e.g., red cell casts) is good evidence for an acute process.

Although as a rule chronic kidney failure is irreversible and slowly progressive, an essential component of the ED evaluation is to exclude the possibility of potentially reversible factors (in effect, ruling out "acute on chronic" renal failure) and to ensure that treatable causes of CKD—disorders that if treated might allow for some return of renal function—have not been overlooked. These potentially reversible factors and treatable causes of CKD are important to keep in mind because they represent the only potential opportunity to reverse the patient's disease rather than simply to manage its results (Box 97-11).

Primary among superimposed reversible factors are those that lead to decreased renal perfusion. Of these, the most common is volume depletion. Regardless of the initiating cause, the process is exacerbated by the diseased kidney's impaired ability to conserve sodium and to concentrate the urine appropriately. Decreased renal perfusion caused by cardiac dysfunction of any cause is another extremely common and potentially reversible factor. An uncommonly encountered but important vascular cause of reversible deterioration of renal function is scleroderma renal crisis, a syndrome of accelerated hypertension and severe vasoconstriction in patients with underlying scleroderma that can be reversed by timely treatment with ACE inhibitors.[18]

Increased catabolism caused by infection, trauma, surgery, corticosteroids, or GI bleeding is another reversible factor that often is responsible for worsening azotemia and the development of uremic symptoms.

Drugs and toxins constitute another important group of reversible factors. Not only may these agents exacerbate renal insufficiency by causing intravascular volume depletion (diuretics), decreased renal perfusion (antihypertensive agents), or increased catabolism (tetracycline); they also can cause ATN (radiographic contrast material), AIN (many drugs), or inhibition of renal prostaglandin synthesis (NSAIDs). Particularly noteworthy is the dramatic decrease in renal function produced when an ACE inhibitor is administered to a patient with renal insufficiency caused by bilateral renal artery stenosis (or renal artery stenosis in a solitary kidney).[50]

Postrenal reversible factors also are important because of their frequency, particularly obstructive disease in the older male patient and reflux nephropathy in the child. Papillary necrosis should remain a consideration in the diabetic patient, the patient with sickle cell disease, and the patient with a history of long-term analgesic use. Stone disease, retroperitoneal fibrosis, and even rarer entities such as ureteral tuberculosis also should not be overlooked.

Finally, treatment of the underlying disorder that has caused the CKD can occasionally result in the return of some renal function, most notably in cases of myeloma kidney, some forms of secondary glomerulonephritis, and severe hypertensive disease. Although this consideration should relate to long-term care and follow-up, it is appropriate that ED management address this issue to ensure that appropriate evaluation and disposition are arranged.

Management

Persons with CKD constitute a group of patients who merit special attention in the ED setting. These patients are susceptible to infection, bleeding, and the numerous other complications associated with renal failure, as well as those that may be associated with the underlying causative disorder. Moreover, these patients are more vulnerable to the effects of any intercurrent illness or trauma. Those who are maintained with chronic hemodialysis or peritoneal dialysis are subject to potential complications from the dialysis therapy itself.

Patients with CKD also are uniquely susceptible to iatrogenic illness. First, they are less able to handle fluid and solute loads than are normal persons. Just as important, the presence of renal failure significantly alters the metabolism and action of many drugs, often in ways that are not predictable (Box 97-12). Thus the dose and schedule of every administered agent, even apparently innocuous ones such as antacids, laxatives, antiemetics, or multivitamin preparations, should be carefully considered.[51] For this purpose,

www.ketabpezeshki.com 66485457-66963820

ready access to a compendium such as the one by Aronoff and colleagues or availability of a hospital pharmacist for frequent consultations is invaluable.[34] In general, consultation with the patient's nephrologist is recommended on completion of the initial ED evaluation, because management and follow-up monitoring after the patient has left the ED often are complex.

In the United States, most patients with advancing CKD eventually will require dialysis, but several true emergencies may develop in the patient with CKD before chronic dialysis has been instituted. Specific diagnostic and therapeutic considerations apply to the management of these conditions regardless of whether they occur in dialyzed or undialyzed patients.

Hyperkalemia

Potentially the most rapidly lethal complication of CKD encountered in the ED setting is severe hyperkalemia. As a rule, this condition is clinically silent until it causes potentially life-threatening manifestations. Accordingly, hyperkalemia must be looked for in every patient with CKD. These patients can become severely hyperkalemic when required to handle even modest exogenous and endogenous potassium loads; moreover, even drugs that have only minimal effects on the serum potassium in normal persons, such as beta-blockers and ACE inhibitors, can cause hyperkalemia in these patients. There is concern that the use of succinylcholine in patients with CKD has the potential to cause rapid deterioration in patients who are already hyperkalemic, although this appears to be rare.

An ECG should be obtained whenever hyperkalemia is a possibility, and if signs of hyperkalemia are noted, appropriate therapy should be started immediately, even before laboratory confirmation of a high serum potassium level. ECG changes may be completely absent even when hyperkalemia is severe, however.[52] Thus a normal ECG does not preclude the need for laboratory confirmation of a normal serum potassium level. A potassium level of 6 mEq/L should be considered potentially dangerous, even though many patients with CKD chronically tolerate levels somewhat above this threshold without ECG changes. A patient with CKD who is in cardiac arrest should be assumed to be hyperkalemic and treated accordingly while the usual resuscitative measures are taken.

The most rapidly effective treatment for hyperkalemia is intravenous calcium, which transiently reverses the cardiac manifestations of hyperkalemia without altering the serum potassium level or total-body potassium (Table 97-2). Calcium should be given to buy time until more definitive measures can take effect. It makes little sense to administer calcium in response to an elevated serum potassium level in the absence of manifestations of hyperkalemia on the ECG.

In treating hyperkalemia, it also is important to keep in mind the CKD patient's limited ability to tolerate volume and solute

Box 97-12 Mechanisms of Drug Toxicity in Renal Failure

Excessive drug level

loads (see Table 97-2). Thus, sodium bicarbonate infusion risks causing volume overload and precipitating pulmonary edema. Intravenous glucose and insulin treatment also entails some volume administration but is much more effective in any case, and hyperkalemia can be controlled for as long as the infusion is continued. Another effective temporizing measure is the administration of inhaled albuterol to promote movement of potassium into cells while more definitive maneuvers are being instituted.[37,38] To remove potassium from the body, dialysis remains the most rapid and effective intervention. Sodium polystyrene sulfonate (Kayexalate), a resin that exchanges sodium for potassium ions, can be administered orally or rectally but is slow acting and only somewhat effective as a temporizing measure until dialysis (if necessary) can be instituted. In patients who still retain some renal function, the most effective way to treat hyperkalemia may be to administer an intravenous diuretic such as furosemide (if the patient is not hypovolemic) and to give volume if necessary. Large doses of diuretic may be necessary for a satisfactory diuresis to be induced. In light of the potential for ototoxicity with the use of loop-active diuretics, these drugs should be administered by slow infusion rather than by bolus and may be contraindicated in patients who also are receiving other potentially ototoxic agents. During the course of any of these therapeutic interventions, both the ECG and serum potassium levels must be monitored frequently.

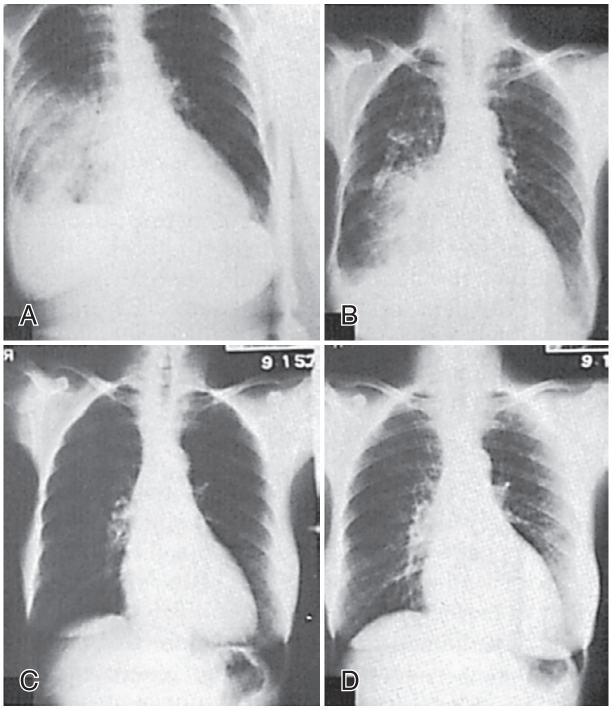

Figure 97-4. Pulmonary edema simulating right lower lobe pneumonia in a dialysis-dependent patient. Marked improvement with decreased infiltrate and return of heart to normal size were evident after dialysis and ultrafiltration. **A,** Chest x-ray film obtained immediately before dialysis shows cardiomegaly and right lower lobe infiltrate interpreted as pneumonia. **B,** Chest x-ray film at 5 hours after initiation of dialysis, with 2-kg weight reduction. The extent of the infiltrate has markedly decreased. **C** and **D,** Lung and heart have returned to normal size. (From Kjellstrand C, et al: In: Drukker W, Parson FM, Maher JF (eds): Replacement of Renal Function by Dialysis. Boston, Martinus Nijhoff, 1983, pp 536-568.)

Pulmonary Edema

Perhaps the most common ED problem in patients with CKD is pulmonary edema secondary to volume overload. Surprisingly, the diagnosis is not always straightforward. A history of increasing dyspnea on exertion or paroxysmal nocturnal dyspnea may be suggestive, but physical examination may not reveal the expected signs of CHF, and even chest radiography may be deceptive (Fig. 97-4).[48] Recent weight gain or a body weight considerably over "dry weight" (typically more than 5 pounds) is the most reliable clue, and in the absence of convincing evidence of another cause for dyspnea, volume overload should be assumed to be the cause, and the patient should be treated accordingly.

Treatment of pulmonary edema in the patient with CKD is of necessity somewhat different from that in other patients (Box 97-13).[53,54] Arrangements for initiation of dialysis should be made as soon as possible because it is the most rapidly effective means to decrease intravascular volume in the absence of renal function. Other immediate measures should be instituted in the meantime. Although such measures may occasionally prove to be effective enough to avoid dialysis temporarily in patients who possess some residual renal function, it should nevertheless be anticipated that the response to even extremely aggressive medical therapy short of dialysis will be inadequate.

Box 97-13 Treatment of Pulmonary Edema in Renal Failure

- Dialysis
  - Hemodialysis
  - Hemofiltration
  - Peritoneal dialysis
- Oxygen
  - Nitroglycerin
  - Nitroprusside
  - Diuretics

The CKD patient with pulmonary edema is placed in the sitting position, and high-flow oxygen is administered by mask. The use of continuous or bilevel positive airway pressure (CPAP or BL-PAP) delivered by face mask has been reported to be a useful adjunct in patients with CKD, as it is in patients without renal failure.[55,56] Sublingual or topical nitroglycerin, or both, can be administered immediately and functions rapidly to reduce both preload and afterload; an intravenous infusion can be begun promptly and titrated to effect. Intravenous nitroprusside may have an advantage in producing more arteriolar dilation if the patient is hypertensive. Diuretics are not expected to be helpful unless the patient has retained a significant level of renal function.

Infection

Because infection is a major contributor to morbidity and mortality among patients with CKD, the possibility of serious infection should be entertained even when the expected classic findings are not all present.[51,57-59] For example, bacteremia may manifest with fever alone, just as in other patients with impaired immunity. Patients with pneumonia may have only vague dyspnea or malaise, symptoms that may be attributed to volume overload or uremia. Thus, all diagnostic possibilities should be pursued, and empirical broad-spectrum antibiotic coverage often is advisable until infection has been ruled out in the hospital. Bacteremia resulting from vascular access infection is quite common in patients receiving hemodialysis, as is peritonitis in patients undergoing peritoneal dialysis.

UTI can occur even in patients with minimal urine output or those with long-standing renal failure. Urinary stasis is undoubtedly a predisposing factor.[59] Upper UTI associated with a clinical picture typical of pyelonephritis or renal colic is seen most commonly in patients with polycystic kidney disease and requires parenteral treatment. A clinical diagnosis can be made presumptively in the ED, but invasive measures sometimes are necessary to document infection and guide therapy. For infected cysts, lipid-soluble antibiotics (e.g., clindamycin, trimethoprim-sulfamethoxazole) offer the best antibiotic penetration; surgical intervention for refractory infection sometimes becomes necessary, however.[61]

www.ketabpezeshki.com 66485457-66963820

Dialysis

Dialysis can normalize fluid balance, correct electrolyte and other solute abnormalities, and remove uremic toxins or drugs from the circulation when the patient's kidneys are unable to do so. Dialysis also can, but generally to a lesser degree, reverse some uremic symptoms and permit better long-term control of hypertension, anemia, and renal osteodystrophy.

The two major dialysis modalities are hemodialysis and peritoneal dialysis. Each is based on a technique whereby the patient's blood comes into contact with a semipermeable membrane on the other side of which is a specially constituted balanced physiologic solution. Water and solutes diffuse across the membrane by moving along concentration and osmotic gradients, effectively normalizing the blood's composition.

Hemodialysis requires special access to the patient's circulation, generally through a surgically created arteriovenous fistula or implanted artificial graft, or through a surgically placed tunneled catheter. The vascular access site must be treated with care because hemodialysis cannot be performed without it. Careless manipulation or puncture can cause bleeding, infection, or thrombosis that may result in loss of the access. The involved arm should not be used for blood pressure determinations, and a tourniquet should not be applied.

In general, blood is drawn and intravenous lines are established in other locations. In exceptional circumstances, if no other site is available and it is essential to obtain blood samples quickly, the fistula or graft may be used, but with precautions: A tourniquet is not applied, the area is cleansed scrupulously before the puncture, and extreme care is taken not to puncture the back wall of the access. After the puncture, firm but nonocclusive pressure is applied for at least 10 minutes. The presence of a thrill both before and after the procedure is documented. Similar precautions are taken in the exceptional cases in which the fistula or graft must be used for intravenous access. If this is done, an automated infusion pump is essential to control the infusion rate into these relatively high-pressure blood vessels.

In *peritoneal dialysis,* the patient's peritoneum functions as the dialysis membrane. Dialysate is infused through a surgically implanted Silastic catheter (Tenckhoff catheter) that penetrates the lower abdominal wall. Fluid exchanges are performed several times per day, typically by the patient at home. As compared with hemodialysis, peritoneal dialysis offers the theoretic advantages of greater patient independence, avoidance of anticoagulation, and smoother control of volume and hypertension without the intermittent rapid shifts of solute typical of hemodialysis. Medications such as insulin and antibiotics can be administered intraperitoneally (IP), allowing smoother absorption and more stable blood levels. The main disadvantage of peritoneal dialysis is a significant incidence of bacterial peritonitis, which is, however, usually readily treatable.

Indications for Dialysis. The decision to initiate chronic dialysis in the patient with CKD generally is made by the patient's nephrologist in the setting of gradually decreasing GFR and slowly progressive manifestations of renal failure. The absolute value of the BUN or serum creatinine generally is used only as a rough guide to when chronic dialysis should be instituted. Provision of vascular or peritoneal access usually has been arranged weeks to months before the anticipated initiation of dialysis, to allow the access site to mature and to minimize any mechanical complications of the procedure.

For patients who come to the ED with AKI, however, as well as for patients with CKD in whom acute problems have developed, it is the emergency physician who must be prepared to make the decision to arrange for dialysis to be provided emergently (Box 97-14). How urgently dialysis must be initiated depends not only on the severity and acuteness of the presenting problem but also on the availability of technical facilities and trained dialysis personnel and the effectiveness of available temporizing measures for the problem at hand.

Box 97-14 Indications for Emergency Dialysis

- Pulmonary edema
- Severe uncontrollable hypertension
- Hyperkalemia
- Other severe electrolyte or acid-base disturbances
- Some overdoses
- Pericarditis (possibly)

The most common problem requiring emergent dialysis, particularly in the patient with CKD, is pulmonary edema secondary to volume overload. In general, the inciting cause is overingestion of fluid and salt in excess of the patient's greatly diminished renal excretory capacity. Despite the effectiveness of temporizing measures, many of these patients require immediate dialysis—either emergency hemodialysis or, in the case of the patient maintained on peritoneal dialysis, intensification of the usual dialysis regimen.

A related problem that may require emergent, or at least urgent, dialysis is malignant hypertension, particularly when associated with hypertensive encephalopathy or cardiovascular decompensation. Because hypertension in most patients with renal failure commonly is volume dependent, correction of volume overload, even if it is clinically not apparent, is a central component of therapy. Temporizing measures such as the administration of intravenous sodium nitroprusside or nitroglycerin often permit hypertension to be controlled sufficiently for dialysis to be delayed for several hours, but prolonged administration of sodium nitroprusside carries an increased risk of thiocyanate toxicity in patients with renal failure. In many cases, hypertension and associated symptoms are difficult to control until dialysis permits volume overload to be corrected. Because the blood pressure often is dramatically responsive to reduction of circulating volume, it is recommended that other antihypertensive agents with more prolonged effects be withheld until after dialysis to avoid hypotension after circulating volume has been acutely reduced.

Severe hyperkalemia is another common indication for emergent or urgent dialysis, particularly in the patient with AKI who is hypercatabolic. In the patient with CKD, hyperkalemia usually is caused by excessive potassium intake, but endogenous causes such as hemolysis or rhabdomyolysis should be kept in mind as well. The available temporizing measures can be used with variable degrees of effectiveness and for different durations to control the serum potassium level, but dialysis remains the most effective means of removing potassium from the body. For rapid control of the serum potassium, hemodialysis, with its high clearance rates, is preferred to peritoneal dialysis.

Other severe electrolyte and acid-base disturbances, including diabetic ketoacidosis,[61] may sometimes necessitate emergent dialysis. Occasional patients with renal failure and severe hypercalcemia uncontrollable by other modalities (e.g., patients with multiple myeloma causing both renal failure and hypercalcemia) may require dialysis. The occasional patient with renal failure in whom severe hypermagnesemia develops after inappropriate therapy or magnesium ingestion may require immediate dialysis to reverse life-threatening paralysis or cardiac dysrhythmia. Severe metabolic acidosis in the setting of renal failure is another indication for emergent dialysis, particularly if volume overload precludes the administration of reasonable amounts of bicarbonate. Of note, bicarbonate also can precipitate tetany and convulsions if administered IV (e.g., to treat acidosis or hyperkalemia) to a patient with hypocalcemia.

www.ketabpezeshki.com 66485457-66963820

A somewhat unusual but related situation is one in which a patient with renal failure has taken an overdose or inadvertently been administered medication that ordinarily is cleared by the kidneys. If the agent is adequately dialyzable and its continued presence in the circulation poses a significant risk to the patient, immediate dialysis can be lifesaving. An example of such a situation is the ingestion of methanol or ethylene glycol by a dialysis patient. Similarly, ill-advised use of magnesium-containing cathartics or phosphate-containing enemas by patients with CKD can lead to dangerous hypermagnesemia and hyperphosphatemia, respectively, and may necessitate urgent dialysis.

The serum creatinine and BUN levels themselves are not considered definitive indications for dialysis. A creatinine of 10 mg/dL or a BUN of 100 mg/dL often is used as a guideline for beginning chronic dialysis in the patient with progressive renal failure. In dialyzed patients, however, the serum creatinine often is considerably greater than 10 mg/dL but is a reflection more of total body muscle mass than the adequacy of dialysis. The BUN is a somewhat better indicator; the level in well-dialyzed persons generally is in the range of 50 to 80 mg/dL and is more than 100 mg/dL in less well-dialyzed patients. Neither blood level, however, correlates more than roughly with uremic symptoms even in undialyzed patients or has any direct bearing on how urgently dialysis should be initiated.

The occurrence of uremic symptoms or signs such as nausea, vomiting, lethargy, or twitching indicates a need for dialysis but does not necessitate immediate initiation of dialysis unless symptoms are severe. Pericarditis, even in the absence of cardiac tamponade, often is considered an indication for urgent dialysis,[62] but it is not uncommon for pericarditis to occur in well-dialyzed CKD patients as well.[63] In a previously undialyzed patient with progressive renal insufficiency, the appearance of pericarditis indicates that it is time to initiate dialysis, although not necessarily on an emergency basis.

Complications of Dialysis Therapy. Optimal ED management of acute problems referred from the dialysis unit, or those occurring at home or in the interdialytic period, requires knowledge of and familiarity with the particular problems associated with CKD and dialysis.[51,57-59] Consultation with the nephrologist or dialysis nurse is important in arranging a consistent care plan for the dialysis patient with an emergent condition and in ensuring appropriate further acute care or follow-up.

Complications of Hemodialysis

Vascular Access–Related Complications

The performance of hemodialysis depends on reliable vascular access, and it is the vascular access device that is responsible for complications of dialysis that most often require evaluation in the ED setting. These problems must be attended to promptly to minimize the risk of losing the patient's dialysis "lifeline."

Bleeding from the dialysis puncture site can occur hours after a hemodialysis treatment, either spontaneously or after inadvertent minor trauma to the site. Such bleeding almost always can be stopped by applying firm pressure to the access site; care should be taken not to occlude and possibly cause thrombosis of the vessel by compressing it too vigorously, and the presence of a thrill immediately after the procedure should be documented in the chart. It may be necessary to keep the patient in the ED for a time to ensure that bleeding does not recur. Recurrent bleeding, especially from an aneurysm or a pseudoaneurysm, is best evaluated by a vascular surgeon.

Similarly, if the patient reports that the thrill in the access has been lost, a vascular surgeon is consulted immediately. Although thrombolytic agents sometimes are used, definitive treatment generally is surgical revision.[57,58] The access device should not be forcefully manipulated or irrigated because rupture of the vessel or venous embolization may result.

Infection of the vascular access is not uncommon and can result in persistent or recurrent bacteremia as well as loss of the access. Infection appears to be a consequence of contamination at the time of puncture for dialysis; most infections are caused by staphylococci typical of skin flora. Infections are more likely to occur in grafts than in native fistulae.[64,65] The signs and symptoms of an access infection—redness, warmth, and tenderness over the site—often are obvious, but in many cases, localizing findings are absent and the patient has only fever or a history of recurrent episodes of fever and documented bacteremia. For this reason, it is common practice to obtain blood cultures for all patients on hemodialysis who have a fever without an obvious source of infection and to treat them presumptively for an access infection.[66] A careful search for other sources of infection is done, however, before nonapparent access infection is concluded to be the cause. Infections such as odontogenic abscess, extremity cellulitis (particularly in diabetics), and perirectal abscess can easily be missed.

Although some nephrologists prefer to admit all dialysis patients with fever to the hospital, management of these patients on an outpatient basis often is possible, provided that they otherwise feel well and do not appear to be septic and provided that they can care for themselves at home and return promptly if their condition worsens. This course is made more practicable by the fact that they can be loaded with intravenous antibiotics that dependably maintain adequate blood levels until the time of the next scheduled dialysis treatment, at which time the culture and sensitivity test results can be checked and therapy adjusted accordingly. Vancomycin 1 to 1.5 g given IV as a single loading dose is the drug of choice in this situation because most access infections are staphylococcal and because this drug is only minimally hemodialyzable and needs to be given only every 5 to 7 days in the chronic dialysis patient. If a gram-negative infection also is thought to be likely, as in a patient who has had recent episodes of gram-negative bacteremia, a loading dose of a second drug (e.g., a third-generation cephalosporin or an aminoglycoside) also can be administered.[66] Patients can be reloaded with these drugs at the end of their next hemodialysis session if culture results prove to be positive.

Non–Vascular Access–Related Complications

The hemodialysis procedure itself, which entails invasion of the vasculature, anticoagulation, and significant shifts of fluid and solutes, often is associated with acute complications such as hypotension, shortness of breath, chest pain, and neurologic abnormalities.

Hypotension

Hypotension that occurs after dialysis most commonly is the result of an acute reduction in circulating intravascular volume and the failure of the patient's homeostatic mechanisms to compensate for it. Because hemodialysis is episodic, each treatment must remove the excess fluid that has accumulated over the period since the last dialysis (generally 2 to 3 days), and patients often are relatively volume-overloaded at the beginning of each treatment. With rapid removal of extracellular fluid, there is inadequate time for transcellular fluid shifts to replace intravascular volume. Antihypertensive medications, particularly beta-blockers, that are required when the patient is in a volume-expanded state can contribute to the hypotension when intravascular volume is normalized.

Most episodes of hypotension that occur during hemodialysis will resolve spontaneously or can be readily managed by either a decrease in blood flow rate or the infusion of small volumes of saline (to effect transient volume expansion) or hypertonic solutions (to reverse transient acute hypo-osmolality). Patients with significant hypotension who do not respond to these maneuvers

From Wolfson AB, Singer I: Hemodialysis-related emergencies: Part I. J Emerg Med 5:533, 1987.

often are brought to the ED for further evaluation. Patients on dialysis should be considered to be at risk for acute myocardial infarction, acute dysrhythmias, and sepsis. These are common causes of hypotension among all patients in the ED, and consideration should first be given to these entities (Box 97-15).[51]

Dialysis patients are commonly treated with epoetin or darbepoetin to prevent severe anemia, but untreated patients typically have low baseline hemoglobin levels, and acute blood loss may result in symptomatic angina or CHF. Serum levels of clotting factors are normal in CKD, but patients are routinely anticoagulated for each hemodialysis treatment. Although transient thrombocytopenia may occur during the dialysis procedure, the qualitative platelet defect characteristic of renal failure represents the most important factor in bleeding that continues beyond the peridialytic period.[67] This abnormality is only partially reversed by dialysis but can be corrected by administration of DDAVP, which increases release of factor VIII–von Willebrand factor (vWF) polymers from vascular endothelium. DDAVP has been used successfully to normalize the bleeding time in preparation for surgery in patients with CKD. Cryoprecipitate and conjugated estrogen both have been shown to produce similar effects for a longer period.[40]

Overt bleeding from the GI tract, often caused by angiodysplasia or peptic ulcer disease, is common and can be dramatic. Occult hemorrhage in other locations, however, can present a diagnostic challenge because symptoms and signs of volume loss tend to be overshadowed by local manifestations of bleeding into a closed space. Thus, spontaneous retroperitoneal or pleural hemorrhage tends to manifest with flank pain or with chest pain and shortness of breath, respectively.

Occasionally, acute hypotension may be caused by anaphylaxis or an anaphylactoid reaction to some component of the dialyzer or the dialysate; these possibilities should be considered if the history is suggestive. Acute pulmonary embolism and acute air embolism are two less likely possibilities. The former, although it does occur occasionally in dialysis patients, is unusual. The latter, although reported occasionally in the past, has been all but eliminated by improved dialysis monitoring equipment and safety mechanisms.

Two additional entities in the differential diagnosis for hypotension are of particular importance in the patient with CKD—acute pericardial tamponade and severe, life-threatening hyperkalemia. Acute pericardial tamponade may be the result of either sudden pericardial hemorrhage or sudden worsening of a formerly compensated pericardial effusion after acute correction of elevated preload. The clinical features of tamponade in the dialysis patient are similar to those in other populations, but the common preexistence of cardiomegaly may make the chest film difficult to interpret unless it shows the typical "water bottle" shape and a definite increase in heart size from previous examinations.

Similarly, an elevated central venous pressure is of little use in differentiating tamponade from underlying right-sided heart failure. Even a bedside ultrasonographic examination that shows pericardial fluid, although suggestive, is not proof that tamponade is present, because many dialysis patients chronically have pericardial effusions that do not cause hemodynamic compromise.[63] Ultrasonographic demonstration of right ventricular diastolic collapse is more specific, but a definitive diagnosis of tamponade depends on the direct demonstration of equal pressures in the right and left atria on cardiac catheterization.

Emergency pericardiocentesis must occasionally be performed in the ED to relieve acute tamponade, but there often is enough time for the patient to be transported to the catheterization suite or operating room for safer and more definitive therapy in a controlled setting. If immediate pericardiocentesis is believed to be necessary, however, the emergency physician should not hesitate to perform this potentially lifesaving procedure, despite the many potential complications and the increased risk of bleeding in patients with CKD. Similarly, in the case of a dialysis patient who is in cardiac arrest, pericardiocentesis generally should be attempted if initial resuscitative efforts have not been successful.

Severe, life-threatening hyperkalemia, although unusual in a dialyzed patient, can occur in the presence of underlying catabolic illness or with a prolonged period of hypotension and low flow. Patients who are hyperkalemic can have profoundly slow heart rates, particularly if they have been treated with beta-blockers or calcium channel blockers. If a dialysis patient is in cardiac arrest, it should be assumed that hyperkalemia is present, and intravenous calcium should be given immediately.

Shortness of Breath

Shortness of breath in dialysis patients generally is caused by volume overload. In the patient who becomes short of breath while being dialyzed, however, other causes must be sought—primarily sudden cardiac failure, pericardial tamponade, pleural effusion, or pleural hemorrhage. Air embolism and anaphylactoid reactions are unusual causes. Often, pneumonia or underlying reactive airway disease is responsible.

Chest Pain

Chest pain during dialysis must be taken seriously because cardiovascular disease is a leading cause of death in patients with CKD, and most episodes of chest pain occurring during dialysis are likely to be ischemic in origin.[68,69] Most dialysis patients have risk factors for coronary artery disease, related to either CKD itself or the underlying condition that led to renal failure, and many have well-documented coronary artery disease.[42,43] CKD is commonly associated with hypertension, hyperlipidemia, carbohydrate intolerance, and disturbances of calcium and phosphorus metabolism. In addition, dialysis patients may be anemic, and many are chronically volume-overloaded. During hemodialysis, these underlying factors may be added to acute physiologic stresses such as transient hypotension and hypoxemia, which often are associated with the dialysis procedure, thereby increasing myocardial oxygen demand while decreasing oxygen delivery.

In evaluating presumed ischemic chest pain in a patient with CKD, it is important to keep in mind the potentially reversible factors that may have precipitated the episode. Particularly when a patient whose angina has been stable begins to experience more frequent or more severe anginal episodes, it should be determined whether increasing anemia, poorly controlled hypertension, or uncorrected volume overload is a factor. Coronary artery disease appears to become symptomatic with a lesser degree of obstruction than in other conditions.

Patients who repeatedly experience chest pain during dialysis should undergo a complete evaluation so that the extent of their coronary artery disease can be defined and optimal management

www.ketabpezeshki.com 66485457-66963820

planned. After repeated, frequent hospital admission to rule out myocardial infarctions because of chest pain during dialysis, it may be reasonable for the patient's nephrologist and cardiologist to set guidelines regarding further admissions.

The presence of renal failure and its associated electrolyte and acid-base disturbances does not in general obscure the usual ECG changes of angina or acute myocardial infarction. The pattern of the change of serum cardiac enzymes with acute infarction also is not altered by CKD, although the baseline level of these enzymes may be higher than in the general population. Troponin appears to perform best as a marker of infarction in patients with CKD.[70-72] Treatment of ischemic chest pain is the same as for other populations.

Among nonischemic causes of chest pain, pericarditis should always be a consideration, even in the well-dialyzed patient. The presentation is essentially the same as in nonrenal patients; fever, a friction rub, or atrial dysrhythmias may be associated findings, and signs of pericardial effusion or early tamponade should be sought. Indomethacin often is effective in relieving pain, but some patients eventually require further measures, such as pericardiocentesis with corticosteroid instillation or pericardial stripping. Patients with pericarditis often receive more frequent or intensified dialysis because pericarditis is thought to be a marker for inadequate dialysis.[62]

Neurologic Dysfunction

Neurologic dysfunction manifesting during or immediately after hemodialysis often is caused by disequilibrium syndrome, a constellation of symptoms and signs that is thought to result from rapid changes in body fluid composition and osmolality during hemodialysis. It usually occurs only in patients with high BUN levels who are just starting hemodialysis. The syndrome does not occur with peritoneal dialysis. Typically, patients have headache, malaise, nausea, vomiting, and muscle cramps, but features in more severe cases may include altered mental status, seizures, or coma. Symptoms resolve over several hours as fluid and solutes are redistributed across cell membranes.

It is dangerous, however, to attribute an altered mental status to disequilibrium syndrome unless other potential causes have been ruled out (Box 97-16), particularly when symptoms persist, fluctuate, or worsen during a reasonable period of observation. Likewise, when seizures occur during dialysis, it is tempting but unwise to attribute them to disequilibrium syndrome without considering other, potentially serious causes, even in patients who have had seizures in the past. In particular, the finding of any new focal neurologic abnormality calls for, at a minimum, an immediate head CT scan to detect intracranial hemorrhage. Similarly, if fever or other evidence of infection is present, meningitis must be a serious consideration. Other considerations include hyperglycemia and hypoglycemia (especially in the diabetic patient), electrolyte abnormalities, hypoxic states, hypotension of any cause, and other toxic or metabolic causes. The treatment of seizures in patients with CKD is essentially the same as in other populations.

Box 97-16 Differential Diagnosis of Altered Mental Status in Dialysis Patients

Structural Conditions
- Cerebrovascular accident (particularly hemorrhage)
- Subdural hematoma
- Intracerebral abscess
- Brain tumor

Metabolic Conditions
- Disequilibrium syndrome
- Uremia
- Drug effects
- Meningitis
- Hypertensive encephalopathy
- Hypotension
- Postictal state
- Hypernatremia or hyponatremia
- Hypercalcemia
- Hypermagnesemia
- Hypoglycemia
- Severe hyperglycemia
- Hypoxemia
- Dialysis dementia

Complications of Peritoneal Dialysis. As with hemodialysis, most of the complications of peritoneal dialysis are related to the dialysis access device, in this case the peritoneal catheter.[51,57] In contrast to hemodialysis, however, the dialytic process in peritoneal dialysis occasions few immediate difficulties. Whatever volume or metabolic problems develop often are a consequence of the fact that the typical patient maintained on peritoneal dialysis is seen by a doctor or nurse only once a month.

Peritonitis is the most common complication of peritoneal dialysis. Fortunately, it is in general much less severe than other types of peritonitis and can be treated readily on an outpatient basis despite the continued presence of a foreign body—the Tenckhoff catheter—in the peritoneal cavity.[57,73] Occasionally, when an episode of peritonitis responds poorly to antimicrobial therapy or when a patient has repeated episodes of peritonitis caused by the same organism, the catheter must be removed and the patient sustained with hemodialysis until the infection is completely cleared and a new catheter can be placed. Repeated infections do, however, carry the risk of permanently altering peritoneal permeability or effective surface area and necessitating a permanent switch to hemodialysis.

Peritonitis in patients on peritoneal dialysis presumably is caused by inadvertent bacterial contamination of the dialysate or tubing during an exchange, or by extension of an infection of the exit site or the subcutaneous tunnel into the peritoneal cavity. A majority of cases of peritonitis are caused by *Staphylococcus aureus* or *Staphylococcus epidermidis*, and most of the remainder (approximately 30%) by gram-negative enteric organisms.[73] Fungal infections are uncommon but generally are refractory to medical therapy and are often considered an indication for catheter removal. Polymicrobial infection suggests direct contamination from the GI tract and mandates a search for the site of perforation or fistula, although such a source is identified in only a minority of cases. No organism is identified in approximately 10 to 20% of cases of peritoneal dialysis–associated peritonitis.

The diagnosis of peritonitis usually is made by the patient when a cloudy dialysis effluent is noted, corresponding with the appearance of white blood cells (WBCs) in the dialysate. Peritonitis is often, but by no means invariably, accompanied by nonspecific abdominal pain, malaise, or fever. Even in the absence of cloudy fluid, when a patient has fever or abdominal symptoms, it is advisable to consider peritonitis and to check the fluid, because early peritonitis may manifest in an atypical manner. In more severe cases, peritonitis is accompanied by nausea, vomiting, severe pain, and hypotension, necessitating hospitalization and consideration of the possibility of acute surgical disease.

In the ED setting the diagnosis of peritonitis is confirmed by the finding of more than 100 WBCs/mm^3 in the peritoneal fluid, with more than 50% neutrophils, or by a positive result on Gram staining. A sample of fluid is obtained for analysis. If a specialized dialysis nurse is available to obtain the fluid, this may be preferable. If not, the fluid is obtained through use of sterile technique. Fluid is sent for cell count and differential, Gram staining, and culture (with use of blood culture bottles).

Peritoneal dialysis–associated peritonitis is treated with an initial intraperitoneal loading dose of antibiotic, followed by a 10- to 14-day course of intraperitoneal antibiotics that are administered by the patient on an outpatient basis. After the diagnosis has been confirmed, consultation with the patient's nephrologist or dialysis nurse specialist is indicated to determine antibiotic therapy as well as a plan for outpatient management and follow-up evaluation or occasionally, if peritonitis is severe or outpatient management is precluded by psychosocial considerations, for hospitalization.

www.ketabpezeshki.com 66485457-66963820

A common treatment regimen is a loading dose of vancomycin 30 mg/kg given IP, followed by further intraperitoneal doses every 5 to 7 days, plus ceftazidime or cefepime 1 g IP or gentamicin 0.6 mg/kg IP. The last two regimens are given as a loading dose followed by maintenance doses administered IP once daily at the time of an exchange.[73] Heparin 500 to 1000 units also may be added to each bag of dialysate for the first few days of treatment to help reduce the formation of fibrin strands that may obstruct the catheter. Patients should be seen by the dialysis nurse in 24 to 48 hours for assessment of the response to therapy and adjustment of antibiotic therapy as necessary after review of the results of culture and sensitivity testing.

Catheter contamination or leaks from the catheter, tubing, or dialysate bag should be managed in the same fashion as for frank peritonitis. The site and cause of leakage are identified, and damaged elements are promptly replaced. Occasionally, with leakage of peritoneal fluid from around the catheter, surgical correction of the underlying problem will be necessary.

Patients who have severe abdominal pain, vomiting, ileus, chills or high fever, or hypotension require hospital admission and management. Likewise, patients with severe underlying illness and those who cannot reliably perform exchanges or administer antibiotics at home also require inpatient management. Dialysis exchanges are continued on the same schedule. The inpatient antibiotic regimen is essentially the same as that used for outpatients.

Perhaps the most serious potential pitfall in caring for the patient maintained on peritoneal dialysis with abdominal pain or other signs of peritonitis is to overlook other serious intra-abdominal conditions whose presentation may mimic that of peritonitis. Patients on peritoneal dialysis are at increased risk for abdominal wall or inguinal hernia because of chronically increased intra-abdominal pressures; previous abdominal surgery also places them at risk for hernia, as well as for obstruction secondary to adhesions. The manifestations of serious disorders unrelated to dialysis (e.g., acute appendicitis, diverticulitis, cholecystitis, acute pancreatitis, ischemic bowel, perforated viscus) also may be attributed to ordinary peritoneal dialysis–associated peritonitis, with the potential for disastrous consequences. The accessibility of the peritoneal fluid for examination may prove to be helpful in documenting the presence of an inflammatory process, but it also has the potential to mislead ED investigation of its cause. A finding of brownish or fecal material in the peritoneal drainage should suggest a ruptured viscus until proven otherwise, and immediate surgical consultation should be sought. Detection of localized tenderness, a palpable mass, or an incarcerated hernia on physical examination can be extremely helpful in making the diagnosis. Abdominal radiography may be useful for demonstrating the presence of ileus, but pneumoperitoneum may reflect only the introduction of air during a recent fluid exchange rather than a perforated viscus.[74] Thus it is important to keep in mind the possibility that disorders other than peritonitis may underlie the patient's symptoms, and astute clinical judgment rather than specific criteria should dictate requests for surgical consultation or decisions regarding hospitalization of the patient for observation.

Infection of the catheter exit site is another relatively common problem for which the patient on chronic peritoneal dialysis may seek care in the ED.[73] This infection tends to be caused by typical skin flora and manifests with the usual local signs of infection. Although not serious in themselves, exit site infections should be taken seriously because they may lead to infection of the subcutaneous tunnel, which can cause repeated episodes of peritonitis and may ultimately necessitate removal of the catheter. Any visible exudate is cultured and Gram stained, and therapy with an oral antibiotic such as trimethoprim-sulfamethoxazole is started, pending the results of culture and sensitivity testing. The patient is instructed to cleanse the site meticulously several times a day using povidone-iodine or peroxide solution.

Tunnel infections can be difficult to detect on physical examination and may be suspected only after the patient has several bouts of peritonitis caused by the same organism. As with other closed-space infections, tunnel infections tend to be difficult to eradicate unless the tunnel is partially unroofed and drained.

Patients maintained on peritoneal dialysis also may come to the ED with any of several basically mechanical problems, of which the most common is failure of the dialysate to drain completely at the time of an exchange. Occasionally this problem is caused simply by kinking or inadvertent clamping of the external catheter or tubing. More often, though, it is the result of catheter obstruction by fibrinous debris or kinking or migration of the catheter within the peritoneal cavity, often associated with constipation. Catheter position is best assessed initially by plain radiography of the abdomen. Specific intervention may be guided by a contrast "catheterogram." Fibrinolytic agents have been used successfully to open occluded catheters, but surgical intervention for catheter replacement often is required.

Severe metabolic disturbances are much less common among patients on peritoneal dialysis than patients on hemodialysis, because in the former group, dialysis is being performed essentially continuously and the blood remains in near-equilibrium with the dialysate. However, significant disturbances do occasionally occur, usually in association with hypercatabolic states, major dietary indiscretions, or significant GI fluid loss. One interesting derangement that occurs occasionally in diabetic patients receiving peritoneal dialysis is a syndrome of severe hyperglycemia (sometimes even despite continuation of the usual insulin dose) resulting from absorption of glucose from hyperosmolar dialysate, with associated nonspecific symptoms of malaise, weakness, and headache. Although glucose levels may be as high as 1500 mg/dL in these patients, they cannot undergo an osmotic diuresis and remain clinically euvolemic. Correction of hyperglycemia must be undertaken carefully to avoid causing rapid osmolar and volume shifts.

KEY CONCEPTS

Acute Kidney Injury

- The causes of AKI can be classified as prerenal, postrenal, and intrinsic renal disorders.
- Management of AKI is directed first at potentially lethal complications such as hyperkalemia or volume overload and then at reversal of the underlying cause of renal dysfunction. It is important to avoid any further hemodynamic or toxic insults to the kidneys.
- The patient's impaired renal function must be considered when fluid is administered and drugs are prescribed.

Chronic Kidney Disease

- Patients with chronic kidney disease have a limited ability to handle fluid and solute loads and have altered metabolism of many drugs; therefore, as with AKI, fluid administration regimens and drug dosages should be checked carefully.
- The most rapidly lethal complication of chronic kidney disease is hyperkalemia. The possibility of this entity should always be considered, and appropriate diagnostic and therapeutic interventions should be instituted when indicated.
- Patients with renal failure often have varying degrees of volume overload. Volume overload generally is the first diagnostic consideration when dyspnea is the presenting complaint.

CHAPTER 98

SEXUALLY TRANSMITTED DISEASES

Diane M. Birnbaumer

PERSPECTIVE

More than 300 million new cases of sexually transmitted diseases (STDs) are diagnosed worldwide each year. In the United States, nearly 20 million new cases of STDs are diagnosed annually, and patients with these infections frequently come to the emergency department (ED) for care.[1] Because EDs often are used as a source of primary health care, their role in screening and treating STDs has been debated. One major area of difficulty in use of EDs for this purpose is that many test results are not available during the ED visit. Treatment decisions are therefore made presumptively, inevitably leading to both overtreatment and undertreatment for STDs. As evidence supporting this concern, one third of patients who test positive for STDs in the ED are not treated during the initial visit, and a majority of untreated patients do not return for subsequent treatment.[1] As a result, emergency providers should weigh the cost of overtreatment against the risk of untreated disease. Because these diseases pose a significant public health risk, it is recommended that patients be treated presumptively in the ED unless good follow-up for test results can be ensured. In addition, to help contain these diseases, many states allow expedited partner therapy (EPT) or patient-delivered partner therapy (PDPT), allowing physicians to prescribe treatment not only for the patients being treated but also for their sexual partners. (Information on EPT and PDPT and the states that allow it is available on the Centers for Disease Control and Prevention [CDC] website [www.cdc.gov]).

Although patients with STDs usually have presenting complaints involving the genitalia, they may also have abdominal, dermatologic, musculoskeletal, neurologic, or systemic symptoms. Prompt and accurate diagnosis prevents both the complications and spread of these diseases.

As with most other illnesses, the history and physical examination provide much of the clinical information needed to diagnose STDs. Patients should be questioned about current and previous symptoms and their duration, as well as any previous history of STDs, recent sexual contacts, use of contraceptives (particularly barrier devices such as condoms), and types of sexual practices; women should additionally be questioned about their menstrual history. Physical examination focuses on the symptomatic area, often the genitalia. Evidence of skin lesions and their type as well as presence of discharge should be noted. Examination of the skin and lymph nodes may be an important component of the examination, particularly in the case of syphilis, gonorrhea, or chancroid. Evidence of septic arthritis on examination of symptomatic joints may indicate gonococcal arthritis and disseminated gonococcal infection (DGI).

The STDs can be divided into two broad categories: those that manifest with genital lesions, with or without adenopathy, and those that are nonulcerative, which most frequently cause genital discharge (Table 98-1).

DISORDERS CHARACTERIZED BY GENITAL LESIONS WITH OR WITHOUT ADENOPATHY

STDs are a well-recognized cause of genital lesions. It is important to note, however, that patients with a "sore" on or near the genitalia or anus may be using this term to refer to genital warts, scabies, premalignant lesions, or other conditions. If an STD is the cause, certain components of the history and physical examination can provide crucial information to help narrow the diagnosis to a specific infection (Table 98-2). The history and physical examination should focus on the characteristics of the lesion or lesions, the presence or absence of adenopathy, and the presence or absence of systemic symptoms. With regard to the lesions, it is important to determine whether they are single or multiple, painful or painless, indurated or soft; whether they have irregular or regular borders; and how they began (e.g., as a vesicle or papule). If the patient has lymphadenopathy, examination will determine if they are unilateral or bilateral and whether the nodes are painful or fluctuant.

In the evaluation of a patient with genital ulcerative lesions, herpes simplex virus (HSV) testing and syphilis serologic studies should be performed; if feasible, a darkfield examination of the lesion scrapings also is useful. In addition, patients should either be tested for or referred for human immunodeficiency virus (HIV) testing, because ulcerative genital lesions increase the risk of acquiring HIV infection.

Comprehensive test results often are not available during the patient's ED visit; therefore treatment is considered for the most likely diagnoses based on history and physical examination findings. The most common ulcerative diseases in the United States are herpes and syphilis; herpes occurs vastly more frequently than does syphilis. In rare outbreaks, chancroid may be the cause of the ulceration.

HERPES

In the United States, genital herpes is the most common cause of ulcerative STDs, with 50 million people infected with the virus and 200,000 to 300,000 new symptomatic cases annually.[2] One in five sexually active adults is infected with the virus, many of whom are asymptomatic. Most commonly caused by HSV type 2, genital herpes also can be caused by HSV-1. In pregnant patients, herpes can cause a devastating congenital infection, although the incidence of such infections has decreased. In addition, HSV infection

www.ketabpezeshki.com 66485457-66963820

plays a major role in the transmission of HIV as herpetic lesions increase the risk of both acquisition and transmission of HIV.

Clinically, genital herpes manifests as either primary herpes infection or recurrence. In primary infections the degree of illness depends on whether the patient has preexisting circulating antibodies to either HSV-1 or HSV-2; in cases of initial genital infection, those with antibodies tend to have a milder syndrome than those without. In cases of primary infection in patients without antibodies, symptoms develop after a 2- to 7-day incubation period. The syndrome begins with genital lesions that may start as vesicles and rapidly become painful, shallow, multiple, and grouped ulcers (Fig. 98-1). In women, these lesions may coalesce into large ulcerations on the perineum (Fig. 98-2). Systemic symptoms may include low-grade fever, myalgias, headache, and fatigue. Adenopathy typically develops during the second or third week of the illness and is bilateral, mildly tender, and nonfluctuant. The local symptoms peak at approximately 8 to 10 days, and it takes 2 to 4 weeks for the lesions to completely heal. Viral shedding can last as long as 3 weeks. In some cases, sacral radiculopathy may develop, with urinary retention, constipation, and sensory changes in the perineal region. Aseptic meningitis and transverse myelitis are relatively uncommon complications. In contradistinction to patients without antibodies, patients acquiring an initial herpes genital infection who have circulating antibodies to the herpesvirus have a milder course, often developing only the genital lesions.

As the symptoms of primary infection recede, the virus settles in the spinal cord ganglia and becomes latent, residing there for the lifetime of the patient. Symptomatic recurrences are the rule, occurring in 60 to 90% of patients. In contrast to the prolonged syndrome and systemic symptoms of primary infection, recurrences are much shorter in duration and tend to cause only mild local symptoms. Many patients will be warned of an impending recurrence by a prodrome, usually characterized by paresthesias, burning, or itching at the site of the subsequent lesions. Although it is known that viral shedding can occur during a recurrence, data suggest that in patients infected with HSV-2, shedding occurs during asymptomatic periods as well.[3]

Population screening with serologic tests for HSV-2 suggests that many people become infected with the virus without symptoms or knowledge of having acquired the infection. Patients with only serologic evidence of past infection may be a potential reservoir for transmission of the virus.

Figure 98-1. Genital herpes lesions on the penile shaft.

Table 98-1 Differential Diagnosis for Sexually Transmitted Diseases

ULCERATIVE	NONULCERATIVE
Herpes genitalis	Gonorrhea
Syphilis (primary)	Chlamydial infection
Chancroid	Nongonococcal urethritis
Lymphogranuloma venereum	Secondary or tertiary syphilis
Granuloma inguinale (donovanosis)	Candidal vaginitis
Molluscum contagiosum	Trichomoniasis
Condylomata acuminata (genital warts)	Bacterial vaginosis
Pediculosis	Endometriosis
Scabies	
Pyoderma	
Trauma	
Excoriations	
Behçet's disease	
Fixed drug eruption	
Yeast infection	

Table 98-2 Characteristics of Ulcerative Sexually Transmitted Diseases

DISEASE	NATURE OF GENITAL ULCER	INCUBATION PERIOD	PAINFUL	INGUINAL ADENOPATHY	DIAGNOSTIC TESTS
Syphilis	Indurated, sharply demarcated, with red, smooth base; heals spontaneously	9-90 days; average 2-3 weeks	No	Firm rubbery nodes; nontender	Darkfield examination; serology
Herpes simplex	Multiple small grouped vesicles on a red base, which form shallow ulcers; may coalesce; resolve spontaneously but recurrence is common	2-7 days	Yes	Bilateral, firm, tender	Culture, serology
Chancroid	Irregular, sharply demarcated borders with undermined edges, shallow, often multiple	3-6 days	Yes	Unilateral most common; overlying erythema, fixed and tender; suppuration may occur	Culture
Lymphogranuloma venereum	Usually single lesion, papule or ulcer, transient, frequently not noticed	5-21 days	No	Unilateral most common; firm, tender, matted, fixed; may suppurate or form fistulae	Lymphogranuloma venereum complement fixation (serology)

Figure 98-2. Coalescent primary herpes lesions on the vulva.

Diagnosis

Although the diagnosis of genital herpes usually is made clinically, this diagnostic strategy is both insensitive and nonspecific. Confirmatory testing should be strongly considered, particularly in women of childbearing age. Several methods are available, including viral culture and antigen testing of the lesions, as well as type-specific viral serologic testing of the blood; a positive result on any of these tests is considered definitive. The Tzanck test, used in the past for diagnosis of herpes infection, is no longer recommended because of its lack of sensitivity.

Although viral culture of a lesion has traditionally been the "gold standard" diagnostic modality, this test has a low sensitivity, takes 3 to 10 days to complete, and has false-negative results ranging from 5 to 20%. Polymerase chain reaction (PCR) testing for HSV DNA is more sensitive and is now the preferred method for making the diagnosis.[3] Recently available serologic testing is type-specific, but patients with newly acquired viral infection may take up to 6 weeks to show positive antibodies.[3] This test is most useful in patients with symptoms consistent with herpes but with negative results on culture or antigen testing. In the patient with a new presentation, PCR testing for HSV DNA is the recommended diagnostic test.

Treatment

Although genital herpes is incurable and outbreaks are self-limited, treatment decreases the duration of symptoms in patients with primary infection, can shorten or abort recurrences, and decreases the amount and duration of viral shedding and therefore potential infectivity. In patients with frequent recurrences, suppressive therapy can decrease the number of these episodes by up to 80%.[4] The mainstay of treatment is therapy with one of the antiviral drugs acyclovir, valacyclovir, and famciclovir[5] (Table 98-3). None of these agents can eliminate the virus, but their use can control symptoms, at least while the drug is being taken. Acyclovir has been shown to be safe for up to 6 years' continuous use as a suppressive agent; the other antivirals have been proven safe for 1 year.[6]

Patient education is critical in cases of genital herpes. The importance of testing the patient's sexual partner or partners should be emphasized, and the patient should be told that he or she can potentially transmit the virus and infect a sexual partner even during asymptomatic periods. If the patient is a woman of childbearing age, she should be instructed to inform her physician of her history of genital herpes if she becomes pregnant.

Neonatal herpes is a devastating and potentially fatal infection seen most often in newborns born to women who acquired the infection near delivery, but it can also be transmitted by women with recurrences and even those who lack a history of clinically evident genital herpes. Cesarean section is the preferred method of delivery if the patient has active lesions at the time of onset of labor. Because the antiviral agents used to treat genital herpes have not been proved safe during pregnancy, the decision to use these agents should be made in conjunction with both the patient and her physician.

BARTHOLIN CYST AND ABSCESS

The Bartholin glands are located inferiorly on either side of the vaginal opening and normally secrete fluid through their openings on the sides of the vestibule. The ducts and glands are palpable or visible only when obstructed, infected, or inflamed. When the duct of the gland becomes obstructed, a simple cyst develops, which usually is painless. Patients with a Bartholin gland cyst typically report a lump at the lateral introitus, and on examination an ovoid mass can be palpated on the mucosal surface of the lateral posterior introitus, just above the posterior fourchette. Treatment usually consists of incision and drainage with local anesthesia with Word catheter placement and sitz baths. Simple packing can be used, but the cavity may need repacking multiple times as the area heals.

A Bartholin abscess develops when a Bartholin cyst becomes secondarily infected. A majority of abscesses involve the anaerobic and aerobic bacteria normally found in the vagina. However, infection may also be caused by sexually transmitted organisms such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Other implicated bacteria include *Bacteroides* species, *Escherichia coli*, and other gram-negative organisms. Patients with a Bartholin abscess have swelling and pain at the lower lateral vaginal opening and may report a lump or mass near the affected labium. On examination, patients may have a swollen and painful labium, and a tender, fluctuant mass can be palpated on the posterolateral margin of the vaginal vestibule. Cellulitis may be present with surrounding edema and erythema.

Treatment consists of incision and drainage, with insertion of a Word catheter. The distal end of this small catheter includes an inflatable balloon. This distal portion is placed into the incision, and the balloon is then inflated with 2 to 4 mL of water or saline. Because the catheter needs to be left in place for 6 to 8 weeks to allow epithelialization along the tract, it is preferable to make the incision on the mucosal surface of the vestibule. This location allows for the protruding portion of the catheter to be tucked into the vaginal opening for patient comfort. Although iodoform gauze can be used as a packing material, the multiple changes necessary to keep the area open during the several weeks of healing make this alternative less desirable. Although incision and drainage are adequate for most patients, management of recurrent infections may require surgical marsupialization, creating a permanent fistula that prevents recurrent abscess formation.

Patients are instructed to start sitz baths within 24 hours of ED discharge to promote drainage. Patients should be referred for follow-up for reexamination of the wound within 48 hours. Because some Bartholin abscesses are caused by multiple organisms, abscess drainage should be cultured and routine testing for STDs performed. Antibiotics usually are not necessary unless

Table 98-3 Treatment Guidelines for Sexually Transmitted Diseases

DISEASE	RECOMMENDED TREATMENT REGIMEN	ALTERNATIVE(S)
Chlamydial infection	Azithromycin 1 g PO × 1 *or* Doxycycline 100 mg PO bid × 7 days	Erythromycin base 500 mg PO qid × 7 days *or* Erythromycin ethylsuccinate 800 mg PO qid × 7 days *or* Ofloxacin 300 mg PO bid × 7 days *or* Levofloxacin 500 mg PO qd × 7 days
Gonorrhea,* uncomplicated urethral, cervical, or rectal infection	Ceftriaxone 250 mg IM × 1 *plus* Azithromycin 1 g PO once	May substitute azithromycin with doxycycline 100 mg PO daily for 7 days
Gonorrhea,* pharyngeal	Ceftriaxone 250 mg IM × 1 *plus* Azithromycin 1 g PO once	May substitute azithromycin with doxycycline 100 mg PO daily for 7 days
Gonorrhea,* adult conjunctivitis	Ceftriaxone 1 g IM × 1 Normal saline irrigation *Consider hospitalization*	
Gonorrhea,* disseminated infection	Ceftriaxone 1 g IM or IV every 24 hours *Strongly consider hospitalization*	Cefotaxime 1 g IV q8h *or* Ceftizoxime 1 g IV q8h
Syphilis; primary, secondary or early latent	Benzathine penicillin G 2.4 million units IM single dose	
Syphilis, late latent	Benzathine penicillin G 2.4 million units IM in three doses, 1 week apart	
Herpes simplex, first episode	Acyclovir 400 mg PO tid × 7-10 days *or* Acyclovir 200 mg PO 5×/day × 7-10 days *or* Famciclovir 250 mg PO tid × 7-10 days *or* Valacyclovir 1 g PO bid × 7-10 days	
Herpes simplex, recurrent	Acyclovir 400 mg PO tid × 5 days *or* Acyclovir 800 mg PO bid × 5 days *or* Acyclovir 800 mg PO tid × 2 days *or* Famciclovir 125 mg PO bid × 5 days *or* Famciclovir 1000 mg PO bid × 1 day *or* Famciclovir 500 mg PO once, then 250 mg PO bid for 2 days *or* Valacyclovir 500 mg PO bid for 3 days *or* Valacyclovir 1 g PO qd × 5 days *or* Valacyclovir 500 mg PO bid × 3 days	
Herpes simplex, suppressive	Acyclovir 400 mg PO bid *or* Famciclovir 250 mg PO bid *or* Valacyclovir 500 mg PO qd *or* Valacyclovir 1 g PO qd	
Chancroid	Azithromycin 1 g PO once *or* Ceftriaxone 250 mg IM once *or* Ciprofloxacin 500 mg PO bid × 3 days *or* Erythromycin base 500 mg PO tid × 7 days	
Lymphogranuloma venereum	Doxycycline 100 mg PO bid × 21 days	Erythromycin base 500 mg PO qid × 21 days

IM, intramuscularly; *IV,* intravenously; *PO,* orally.
* Because of resistance, quinolones are no longer recommended for the treatment of gonorrhea. Also, recent increases in cephalosporin resistance led to the removal of the previously recommended cefixime as treatment for uncomplicated gonorrhea.

significant surrounding cellulitis is present. If deemed necessary, patients should be treated with appropriate antibiotic therapy to cover coliforms as well as sexually transmitted infections, including *Chlamydia* and *N. gonorrhoeae.*

SYPHILIS

Syphilis, known as the "Great Imitator," is caused by the spirochete *Treponema pallidum* and earns its nickname from its ability to infect virtually any organ of the body and cause multiple symptoms.

The organism is fragile and does not survive on dry surfaces. Transmission occurs during exposure of moist skin to an infected area. Although transmission usually involves the genitalia, inoculation can occur virtually anywhere on the body. The incidence of primary and secondary syphilis in the United States hovers between 7000 and 10,000 cases per year.[7]

If untreated, syphilis typically progresses through several stages, as follows.

1. *Primary.* The primary lesion, called a *chancre,* occurs after an incubation period that varies from 9 to 90 days, averaging 2 to 4 weeks. This lesion occurs at the site of inoculation and begins as a papule that then ulcerates. Typically the chancre is solitary and painless and has a smooth, slightly raised edge, with sharply defined borders and a clean base (Fig. 98-3); occasionally patients have more than one lesion (Fig. 98-4). Without treatment the chancre lasts for 2 to 6 weeks and resolves spontaneously, and the disease then progresses to the secondary stage. Adenopathy is not a predominant feature of primary

www.ketabpezeshki.com 66485457-66963820

Figure 98-3. Chancre of primary syphilis on the penis.

Figure 98-4. Two lesions of primary syphilis on the penile shaft.

syphilis. If the chancre is on the genitalia, bilateral, painless, nonfluctuant, and slightly enlarged inguinal adenopathy may develop several days after appearance of the primary chancre.

2. *Secondary.* Manifestations of the secondary stage of syphilis begin 5 to 8 weeks after resolution of signs and symptoms of the primary stage. The most common manifestation is a total body rash (Fig. 98-5). This rash

Figure 98-5. The rash of secondary syphilis.

Figure 98-6. Palmar rash caused by secondary syphilis.

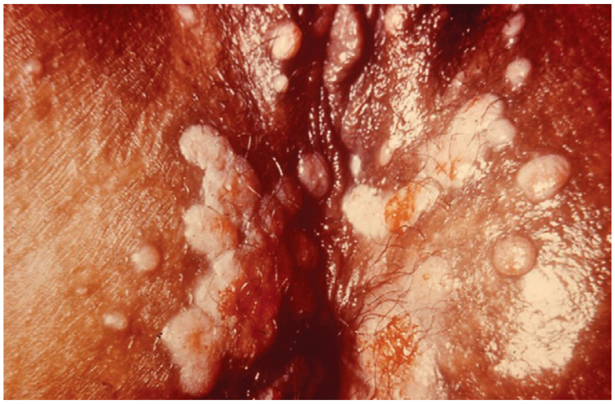

Figure 98-7. Condylomata lata of secondary syphilis.

begins on the trunk as a fine macular rash, which then spreads outward to the arms and legs and may involve the palms and soles (Fig. 98-6). As it progresses, it becomes papulosquamous and may appear slightly annular, often resembling the rash of pityriasis rosea. Mucous patches can be seen on the tongue, which are the oral manifestations of the skin rash. Condylomata lata (Fig. 98-7) can also develop; these lesions are broad-based papules with flat moist tops, occurring in the perineal region, and may involve the anus, the skin between the buttocks, and the labia. Constitutional signs and symptoms are common during this stage, including fatigue, low-grade fever, malaise, headache, arthralgias,

www.ketabpezeshki.com 66485457-66963820

and generalized lymphadenopathy. Adenopathy may occur virtually anywhere in the body, including epitrochlear node involvement. The nodes are discrete, nontender, and rubbery. As with the primary stage, the manifestations of secondary syphilis will resolve spontaneously if the condition goes untreated, and the infection then enters the latent or tertiary stage.

3. *Latent.* After resolution of the clinical manifestations of secondary syphilis, patients enter the latent phase, which is defined as seroreactivity for syphilis without evidence of disease. As there are no clinical signs and symptoms during this stage, laboratory testing is the only means to identify infected persons. Latent syphilis is divided into two categories: *early latent* syphilis, acquired within the preceding year, and *late latent* syphilis, the designation for all other cases of latent syphilis or for latent syphilis of unknown duration.
4. *Tertiary.* In the immunocompetent individual, signs and symptoms of tertiary syphilis may appear after a latent period of at least 3 to 4 years. This stage predominantly involves the cardiovascular and nervous systems. Presenting conditions may include a thoracic aortic aneurysm, meningitis, peripheral neuropathy (tabes dorsalis), or gummatous lesions of the mucous membranes. Although common in the preantibiotic era, tertiary syphilis is now uncommon in the United States.

Diagnosis

The only rapid means of diagnosing syphilis is the darkfield examination. This method involves viewing scrapings or fluid from primary or secondary syphilis lesions under a darkfield microscope to identify the spirochete. Unfortunately, the sensitivity of darkfield microscopy is approximately 80%, and many hospitals and clinics do not have this technique routinely available.[5]

Serologic testing is the current standard for diagnosing secondary, latent, and tertiary syphilis. In primary syphilis, one-time testing is less reliable, and follow-up testing may be necessary to confirm the diagnosis. There are two types of serologic tests: *nontreponemal*—the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests—and *treponemal*—microhemagglutination assay for *T. pallidum* (MHA-TP) and fluorescent treponemal antibody absorption (FTA-ABS) test. Both types of tests are necessary for definitive diagnosis, although the nontreponemal test is used for screening, with treponemal testing used for confirmation. Nontreponemal tests measure nonspecific antibodies in serum from patients with syphilis, and the titers tend to vary with the stage and activity of disease. These tests involve quantitative measurement of antibody and become positive approximately 2 weeks after the primary chancre appears. Titers are used to follow response to treatment. Because these tests are nonspecific for the treponeme and false-positive results can occur, positive test results should be confirmed with the more specific treponemal tests. Treponemal tests measure antibodies specific to the spirochete *T. pallidum.* These tests are more expensive and difficult to perform than the nonspecific tests, and because their titers do not predictably vary with treatment, the main value of these tests is in confirming positive findings on nontreponemal tests.[5]

Treatment

A one-time dose of the long-acting formulation of penicillin G benzathine, 2.4 million units intramuscularly (IM), is the regimen of choice for treating primary and secondary syphilis[5] (see Table 98-3 for treatment of latent and tertiary syphilis). It is crucial that the long-acting form of penicillin G benzathine be used; the half-life of an alternative preparation comprising both penicillin G benzathine and penicillin G procaine (i.e., Bicillin C-R) is too short, which has resulted in treatment failures.[5] Sexual partners need to be evaluated; partners within the last 90 days should be tested but treated presumptively, and partners from more than 90 days before diagnosis should be evaluated and treated if indicated. Because syphilis increases the risk of acquisition of HIV, all patients should be referred for HIV testing. For response to treatment to be ensured, patients should be reexamined clinically and serologically 6 and 12 months after treatment. Successful treatment is confirmed by either a nonreactive nontreponemal test or a fourfold or greater decrease in titers after 6 months. Because syphilis is a reportable disease, patients with positive test results should be reported to the public health department.

Because congenital syphilis can be devastating, pregnant patients with syphilis pose a unique and significant concern. Parenteral penicillin G is the only agent with documented efficacy in these instances. Therefore in pregnant women with a reported penicillin allergy who have syphilis at any stage, treatment with penicillin is still recommended after desensitization.[5]

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is a chronic STD caused by specific serotypes of *C. trachomatis.* Although this disease is prevalent in many tropical countries, it is rare in the United States and is seen either in patients who have traveled to endemic areas or in localized outbreaks in patient populations such as men who have sex with men. The incubation period ranges from 3 days to 3 weeks. In cases of genital exposure, the initial infection manifests as a transient genital lesion that is small and painless and often goes unnoticed by the patient. Patients typically are seen in the secondary stage with lymphadenitis, characterized by involvement of the lymphatic channels and nodes of the genitalia, pelvis, and rectum. This lymphadenitis begins at 7 to 30 days after the primary lesion disappears. Inguinal lymphadenopathy most often is unilateral, and enlargement of the glands above and below Poupart's ligament gives the characteristic LGV "groove sign." The enlarged nodes often are painful, with overlying erythema, but usually are not fluctuant or at most are minimally so. The nodes either eventually break down, with the formation of multiple draining sinuses, or form a hard inguinal mass without suppuration. The late complication of distal lymphedema results from the blockage of lymphatic channels.

Patients with rectal exposure may have proctocolitis, manifesting with mucoid and/or hemorrhagic rectal discharge with anal pain, fever, constipation, and/or tenesmus. Untreated, these patients may develop colorectal fistulae and strictures.

Diagnosis

Although serologic testing is available, the diagnosis of LGV is usually based on the clinical picture, epidemiologic information, and the exclusion of other causes of inguinal lymphadenopathy and genital ulcers.

Treatment

Treatment is curative and is crucial to prevent permanent tissue damage. The preferred treatment is with doxycycline, 100 mg orally (PO) twice daily for 21 days; erythromycin base 500 mg PO four times daily for 21 days is an alternative regimen.[5] Patients should refer their sexual partners from within the previous 60 days for evaluation and treatment, and all patients should be referred for HIV testing.

www.ketabpezeshki.com 66485457-66963820

Figure 98-8. Ulcerative lesions of the penis from chancroid with accompanying fluctuant, tender, erythematous lymphadenitis (bubo).

CHANCROID

Chancroid is caused by *Haemophilus ducreyi,* a small gram-negative bacterium. This disease is common in developing countries but rare in the United States, with usually less than 100 cases reported annually to the CDC. Despite being relatively rare, outbreaks of chancroid have been reported in the United States, and physicians should be aware of the characteristics of this disease to permit recognition of these occasional outbreaks when they occur.

Clinically, chancroid is characterized by multiple painful genital ulcerations and inguinal bubo formation (Fig. 98-8). After an incubation period of less than 1 week, a short-lived, small, tender red papule appears at the site of inoculation. This lesion rapidly ulcerates, followed by the formation of multiple shallow, painful ulcers with sharply demarcated edges and purulent bases. These lesions last 1 to 2 weeks, and in some patients they may coalesce. Inguinal lymph node involvement is seen in 50% of patients, manifesting 1 week after the ulcers appear. Typically, a unilateral large, painful, fluctuant lymph node (bubo) develops in the groin. Overlying skin is thinned and erythematous, and suppuration is common. These buboes can spontaneously rupture.

On a clinical basis, it may be difficult to distinguish chancroid from genital herpes. The presence of a large, fluctuant bubo strongly suggests chancroid. However, if only ulcers are present, the patient can have either disease. Because herpes is several orders of magnitude more common in the United States than chancroid (which tends to occur in isolated outbreaks), herpes is the first diagnosis to be considered.

Diagnosis

H. ducreyi is difficult to culture, so the diagnosis is based on clinical presentation and often is one of exclusion, after other diseases such as herpes and syphilis have been ruled out by testing. Definitive diagnosis requires isolation and identification of *H. ducreyi,* a fastidious organism requiring a special growth medium that is not routinely available. Because definitive diagnosis can be elusive, a "probable diagnosis" can be made if all of the following criteria are met: (1) The patient has one or more painful genital ulcers; (2) the patient has no evidence of *T. pallidum* infection on dark-field examination or serologic testing at least 7 days after onset of the ulcers; (3) the clinical presentation, appearance of genital ulcers, and, if present, regional lymphadenopathy are typical for chancroid; and (4) results of HSV testing performed on the ulcer exudates are negative.[8] When local outbreaks are known, the microbiology laboratory can prepare the special medium required for growth of the organism to confirm specific cases, as well as to follow containment of the infection.

Any of the following four curative treatment regimens may be used: a single dose of azithromycin 1 g PO, a single dose of ceftriaxone 250 mg IM, ciprofloxacin 500 mg PO twice daily for 3 days, and erythromycin base 500 mg PO three times daily for 7 days (see Table 98-3).[5] Coinfection with syphilis or HSV occurs in approximately 10% of patients who have chancroid acquired in the United States, so patients should be evaluated for these infections. Because chancroid is associated with increased risk of HIV transmission, all patients should be referred for HIV and other STD testing. Sexual partners of patients with chancroid should be examined and treated if sexual contact with the patient occurred during the 10 days preceding the patient's onset of symptoms, even if the partners are asymptomatic. To confirm response to treatment, patients should be referred for reexamination 3 to 7 days after initiation of therapy.

Drainage of buboes is not routinely recommended because appropriate antibiotic treatment typically results in a good clinical response. If deemed necessary, needle aspiration of nodes in the superior cephalic aspect of the fluctuant area can be performed; reaspiration usually is usually not necessary because the adenopathy responds quickly to antimicrobial treatment. On rare occasions, incision and drainage may be necessary.

GRANULOMA INGUINALE

Granuloma inguinale (donovanosis) is caused by *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*), an intracellular gram-negative rod. The disease is rare in developed countries but is endemic in tropical and semitropical regions, including India, Papua New Guinea, central Australia, the Caribbean, and southern Africa. The disease is presumed to be sexually transmitted, with an incubation period of 8 to 80 days.

Clinically, the disease manifests as chronic, painless, progressive ulcerative lesions on the genitalia or perineum. The lesions are irregular, clean-based granulomatous ulcers that are highly vascular (giving the classic "beefy red appearance") and bleed easily on contact. The ulcer feels hard when palpated. Regional lymphadenopathy does not occur. As the lesion enlarges, it can be quite mutilating to the genitalia, causing urethral stenosis over a period of months to years. Without adequate treatment, it may result in lymphatic obstruction, producing genital edema and eventually lower extremity elephantiasis. In men the sites of predilection are the prepuce, the coronal sulcus, and the frenulum. In women, lesions typically are found on the labia, but vaginal and cervical lesions also can occur.

Diagnosis is difficult and requires identification of the infectious agent, which appears as short, pleomorphic rods with bipolar staining. Donovan bodies may be seen within histiocytes on microscopy of tissue crush preparation or biopsy specimen. The causative organism is very difficult to culture, so visualization of the organism with appropriate staining is the primary means of diagnosing the disease.

Treatment halts progression of the lesions, but relapse can occur 6 to 18 months after apparently successful treatment. The CDC-recommended regimen is doxycycline 100 mg PO twice daily for at least 3 weeks or until the lesions have healed. Alternative regimens include azithromycin 1 g PO once a week, ciprofloxacin 750 mg PO twice a day, erythromycin base 500 mg PO four times daily, and trimethoprim-sulfamethoxazole, one double-strength (160 mg/800 mg) tablet PO twice daily; each regimen should be continued for 3 weeks or until the lesions have healed.

Clinical follow-up visits are recommended until signs and symptoms have resolved. Persons who have had sexual contact with the patient within 60 days of symptom onset should be examined and offered therapy. Patients should be screened for other STDs.

www.ketabpezeshki.com 66485457-66963820

Figure 98-9. Genital warts from human papillomavirus infection.

CONDYLOMATA ACUMINATA

Anogenital warts are caused by the human papillomavirus (HPV), and more than 40 types of HPV can infect the genital tract. HPV infections most often are sexually transmitted, and lesions are most common at the site of greatest trauma during sexual intercourse. Most cases of HPV infection are asymptomatic or subclinical, with only approximately 1% resulting in clinically apparent warts. Most visible genital warts are caused by HPV types 6 and 11 and are benign. Other HPV types (i.e., 16 and 18) have been associated with external genital squamous intraepithelial neoplasia in both men and women and are considered to be the cause of most cases of cervical cancer.

In clinically apparent cases, warts may be single or multiple (Fig. 98-9). Warts on warm, moist, nonhairy skin tend to be soft and nonkeratinized, whereas those on dry, hairy skin are more firm and keratinized. The lesions can be broad based, pedunculated, or pigmented. Depending on the size and location, warts can be asymptomatic or painful, friable, or pruritic. Warts that are indurated, fixed, ulcerated, and darkly pigmented may require biopsy to rule out carcinoma.

Diagnosis usually is made clinically by visual inspection. In women, a speculum examination is indicated to evaluate the patient for intravaginal and cervical lesions. Occasionally, HPV infections may be confused with the condylomata lata of syphilis. If there is any doubt about the diagnosis, or if warts have high-risk characteristics, biopsy and darkfield microscopy of tissue are indicated, along with serologic testing for syphilis.

Treatment is aimed at removal of symptomatic warts. Although wart-free periods may be achieved, treatment has not been shown to affect the course of disease or to reduce infectivity. If left untreated, visible genital warts may resolve spontaneously, remain unchanged, or increase in number.

Many treatment options are available, although no specific treatment has been proved to be superior to another; all have significant failure and recurrence rates. For patient-applied regimens, the patient should be able to identify and reach the warts to be treated with these methods. Provider-administered regimens often require ongoing treatments on a weekly basis and usually are best administered by a primary care physician, who can monitor the patient's response to therapy. In general, warts located on moist surfaces respond better to topical treatments than do the keratinized warts found on drier surfaces. Patients should be instructed to watch for recurrences, which are most common in the first 3 months after treatment.

Patient preference, available resources, and physician experience should guide treatment. Most of these treatments are administered by the patient's primary care physician and not through the ED. Regimens can be divided into patient-applied and provider-administered treatments.

Patient-applied regimens include the following:

- Podofilox 0.5% solution or gel, applied twice a day for 3 days, followed by 4 days of no therapy—which may be repeated, as necessary, for up to four cycles.
- Imiquimod 5% cream, applied once daily at bedtime, three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6 to 10 hours after application.
- Sinecatechins 15% ointment, applied three times daily with a finger to ensure complete wart coverage with a thin layer of ointment; the ointment is not washed off. Treatment is continued until complete clearance of warts has been achieved, but no longer than 16 weeks.

Provider-administered regimens include the following:

- Cryotherapy with liquid nitrogen or cryoprobe, which may need to be repeated every 1 to 2 weeks
- Podophyllin resin, 10 to 25% in a compound tincture of benzoin
- Trichloroacetic acid (TCA) or bichloroacetic acid (BCA), 80 to 90%
- Surgical removal

Podophyllin and podophyllum resin should be avoided in pregnant patients because of possible teratogenic effects. Imiquimod also is not approved for use during pregnancy. Immunosuppressed patients are more likely to demonstrate a poor response to treatment, increased relapse rates, and dysplasia and need close follow-up. All patients need screening for other sexually transmitted infections. Treatment of partners is not necessary.

In 2006 the U.S. Food and Drug Administration (FDA) licensed the HPV vaccine, which covers the four virus types that are responsible for 70% of cases of cervical cancer and 90% of anogenital warts. The vaccine is virtually 100% effective if administered before first sexual contact. Currently the vaccine is recommended for males aged 9 to 26 years to prevent genital warts and for females aged 11 and 12 years and those aged 13 to 26 years who were not fully vaccinated when they were younger.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a condition characterized by multiple rounded, domed, waxy papules ranging from 2 to 5 mm in size that are often umbilicated. They are caused by a benign virus inoculated on the skin. In adults the virus is commonly sexually transmitted and causes few lesions, often limited to the perineum, genitalia, lower abdomen, or buttocks. It is usually a self-limiting disease in healthy adults and rarely needs specific treatment.

DISORDERS CHARACTERIZED BY GENITAL DISCHARGE

Patients with diseases that fall into the group of disorders characterized by genital discharge tend to have urethral or vaginal discharge and do not have ulcerations or significant lymphadenopathy. These infections include chlamydial infection,

www.ketabpezeshki.com 66485457-66963820

gonorrhea, nongonococcal urethritis, trichomoniasis, bacterial vaginosis, candidiasis, and pelvic inflammatory disease (PID). Bacterial vaginosis and candidiasis are not typically considered to be sexually transmitted conditions but often are diagnosed in patients undergoing evaluation for STDs. Chlamydial infection and gonorrhea can also cause vaginal discharge, especially in the setting of mucopurulent cervicitis, and both tend to cause urethral discharge in men. These two organisms commonly cause coinfections, and clinical manifestations of these two infections are similar. It usually is not possible to distinguish between the two diseases on the basis of signs and symptoms alone, and patients often are appropriately treated presumptively for both infections (see Table 98-1).

CHLAMYDIAL INFECTION

In the United States, chlamydial infection is diagnosed in more than 1 million people annually, making it the most commonly reported STD.[1] The causative organism is *C. trachomatis,* an obligate intracellular organism that infects columnar and pseudostratified columnar epithelial cells. Although infection with *C. trachomatis* can cause a variety of symptoms, including urethritis, cervicitis, epididymitis, proctitis, prostatitis, PID, and perihepatitis (also known as *Fitz-Hugh–Curtis syndrome*), asymptomatic infection is common.

Symptoms appear after an incubation period of 1 to 3 weeks. Although urethritis is the most common manifestation in men, men also can have epididymitis, or both in combination. When symptomatic, women may report symptoms and signs ranging from dysuria to systemic illness related to peritonitis. Often, however, the presenting manifestations in women are vague and nonspecific: dyspareunia, vaginal discharge or bleeding, or abdominal or pelvic pain, or some combination thereof. Unfortunately, infection is commonly asymptomatic; estimates show that up to 75% of infected women and 50% of infected men have no symptoms.[9] The highest rate of infection is in sexually active adolescent females, with infection rates as high as 10% in this group.[9] Of note, PID, with its increased risk of subsequent ectopic pregnancy and infertility, develops in up to 40% of women with untreated chlamydial infection.[5] Because of the high rate of asymptomatic infection and the increased risk for development of PID and its sequelae after chlamydial infection, screening of high-risk patients (e.g., those with multiple sexual partners) for disease may be appropriate in the ED, as long as adequate follow-up is ensured. The CDC recommends *Chlamydia* testing for all women 25 years of age or younger, for older women with risk factors (a new sexual partner or multiple sexual partners), and for all pregnant patients.[5]

In the past the gold standard modality for diagnosing chlamydial infection was cell culture, but it has fallen out of favor as it is labor-intensive, it is fraught with difficulties, and definitive results take days. Although other nonculture techniques (DNA probe and latex agglutination testing) have been used since the 1990s to make the diagnosis of chlamydial infection, the high sensitivity and specificity of nucleic acid amplification techniques (NAATs) has made them the diagnostic methods of choice. All of these techniques amplify nucleic acid sequences specific to the organism being tested and do not require viable organisms. NAATs have sensitivity rates better than those for culture (greater than 90%, versus 60-80%),[10] with specificity greater than 99%,[10] and they are more sensitive than other nonculture tests (DNA probe testing, latex agglutination testing). NAATs can be performed on swabs (endocervical or urethral) and urine. Urine screening with NAATs is adequate for symptomatic male patients, and urethral swabs generally are not necessary[10]; either vaginal or urine specimens are adequate for testing in women.[10]

Treatment of chlamydial infection consists of azithromycin 1 g PO in a single dose or doxycycline 100 mg PO twice daily for 7 days. Coinfection with gonorrhea is common, so unless gonorrhea is definitively ruled out, patients should be treated for both infections. Patients should be instructed to abstain from sexual intercourse for 7 days after completion of treatment (either single-dose therapy or the 7-day regimen of doxycycline). Sexual partners within the previous 60 days (and, if the last sexual encounter was more than 60 days before symptom onset, the most recent sexually partner) need to be evaluated, tested, and treated, and the index patient also should be instructed to abstain from sexual intercourse until all partners have been treated. Follow-up testing for cure is not required unless symptoms persist or reinfection is suspected.

NONGONOCOCCAL URETHRITIS

Nongonococcal urethritis is characterized by urethral discharge, dysuria, or urethral pruritus and, although most commonly diagnosed in men, also can be seen in women. Although the condition is often caused by *C. trachomatis* or *N. gonorrhoeae,* other organisms such as *Mycoplasma* and *Ureaplasma* also may be causative agents. All patients with suggestive symptoms should be evaluated for both gonorrhea and chlamydial infection with NAATs. The diagnosis is confirmed by Gram's stain (more than five white blood cells [WBCs] per high-power field and no gram-negative diplococci), a positive result on the leukocyte esterase test on urinalysis, or more than 10 WBCs per high-power field on urinalysis.

Treatment consists of azithromycin 1 g PO in a single dose or doxycycline 100 mg PO twice daily for 7 days.[5] In women with dysuria, other causes or coinfections should be ruled out, including chlamydial infection, trichomoniasis, and candidiasis. Patients with persistent symptoms despite adequate initial therapy (appropriate regimen and completion of treatment course) should be reevaluated for the accuracy of diagnosis. If the diagnosis was accurate, the patient should be treated with metronidazole 2 g in a single dose or tinidazole 2 g in a single dose; azithromycin 1 g as a single dose should be added if it was not used in the first treatment regimen.[5]

GONORRHEA

After chlamydial infections, gonorrhea is the second most frequently reported STD, with an estimated 300,000 new *N. gonorrhoeae* infections in the United States each year.[1] Because infection involves columnar or transitional epithelium, this organism can affect the urethra, rectum, cervical canal, pharynx, upper female genital tract, and conjunctival sac.

The most common clinical presentation in men is acute urethritis, characterized by dysuria and a penile discharge (Fig. 98-10) starting within 1 to 14 days of exposure. On examination, findings may include urethral meatal erythema and a purulent urethral discharge. Men may also have epididymitis, although this is uncommon.

In women, primary infections are often asymptomatic or produce only vague symptoms, such as vaginal discharge, abnormal vaginal bleeding, abdominal or pelvic pain, dyspareunia or dysuria, and frequency. Patients may not seek treatment until after the emergence of complications such as PID, which develops in up to 20% of women with untreated gonorrhea.[5] Like chlamydial infection, symptomatic and asymptomatic gonococcal infection can cause PID with consequent tubal scarring that may lead to infertility or ectopic pregnancy.

Gonorrhea also can involve the oropharynx and the anorectal area. Gonococcal infection of the pharynx often is asymptomatic, but in symptomatic cases, patients develop sore throat and

www.ketabpezeshki.com 66485457-66963820

Figure 98-10. Purulent urethral discharge in a patient with gonorrhea.

exudative tonsillitis. Most cases are self-limited. Anorectal involvement is more common in persons who engage in receptive anal intercourse but can occur in women from contamination from cervicovaginal secretions. Like pharyngeal infection, it often is asymptomatic. When the condition is symptomatic, patients report rectal discomfort or pain, tenesmus, constipation, dyspareunia, pruritus ani, and purulent or mucoid anal discharge or bleeding. Anoscopy reveals friable mucosa and mucopurulent exudate.

Gonococcal conjunctivitis can be a sight-threatening infection, so recognition of this form of infection is crucial. This infection can occur in newborns, in whom it is acquired during passage through an infected birth canal, and in adults, who often acquire the infection by direct inoculation from organisms on the fingers and then rubbed onto the eye. Symptomatic conjunctivitis is characterized by beefy red conjunctiva, chemosis, and purulent eye discharge that may be copious. If untreated, it can progress to corneal ulceration or, in severe cases, gonococcal endophthalmitis and globe perforation.

DGI results from gonococcal bacteremia and occurs more frequently in women than in men. Typically, it manifests as the arthritis-dermatitis syndrome, characterized by a combination of any or all of the following: fevers, chills, monoarticular or oligoarticular arthritis or arthralgias, rash, and tenosynovitis. The rash of DGI consists of petechial or pustular acral skin lesions, usually found peripherally on the extremities. The lesions are described as necrotic pustules on an erythematous base and are tender to palpation. These lesions represent the consequence of septic emboli to small blood vessels during bacteremia. Joint involvement, the second most common manifestation of DGI, manifests with an acute monoarticular or oligoarticular septic arthritis or arthralgias. The knees are most commonly involved, followed by elbows, ankles, wrists, and small joints of the hands and feet. The involved joint is erythematous and warm, often has an effusion, and is painful on range-of-motion testing. Other manifestations of DGI, which are rare, include hepatitis, myocarditis, endocarditis, and meningitis.

Definitive diagnosis of DGI is confirmed by isolating gonococci from the blood, synovial fluid, or infected skin; unfortunately, cultures from these sites have relatively poor sensitivity. Presumptive diagnosis of DGI is based on the appropriate clinical presentation, plus isolation of gonococci from a source site.

Diagnosis

Diagnostic tests for gonorrhea include Gram staining, culture, and NAATs. Gram staining is most useful in symptomatic men with urethritis and in patients with gonococcal conjunctivitis. In these cases it is an excellent diagnostic test, with a sensitivity and specificity approaching 100%,[5] and results are available rapidly.

Culture for *N. gonorrhoeae* can be used to isolate the organism for antimicrobial testing and determination of antibiotic sensitivities, and is useful in areas of rapidly emerging resistance. The sensitivity of this test may be significantly decreased by improper specimen collection and handling. For the yield of gonococcal culture to be maximized, inoculation of the specimen immediately after collection directly onto the appropriate medium optimizes viability of the organisms. If the specimen is from a sterile site, such as cerebrospinal fluid or synovial fluid, a nonselective medium such as chocolate agar is best. Specimens from nonsterile sites such as the cervix, urethra, rectum, or oropharynx, where normal bacterial flora is present, should be inoculated on selective media such as Martin-Lewis agar. If not transported immediately to the laboratory, specimens should be incubated at 35 to 36.5° C in a carbon dioxide–enriched atmosphere after collection and transported to the laboratory in a carbon dioxide–enriched atmosphere.

NAATs have good sensitivity and excellent specificity for detection of gonorrhea from endocervical, urethral, and urine samples. These tests are approved by the FDA for the detection of *N. gonorrhoeae* in endocervical swabs from women, urethral swabs from men, and urine from both men and women. The sensitivities of NAATs are superior to those of culture but may vary by type of NAAT.

Although NAATs are useful for diagnosis of cervical and urethral gonorrhea, they have not been cleared by the FDA for diagnosis of gonorrheal infection of the rectum, pharynx, or conjunctiva or from synovial fluid and cerebrospinal fluid; culture is required for diagnosis of organisms from these sites. In addition, culture is the diagnostic method of choice if it is necessary to determine the organism's sensitivity to specific antibiotics.

Treatment

The ability of *N. gonorrhoeae* to develop antimicrobial resistance is closely monitored by the CDC's Gonococcal Isolate Surveillance Project (GISP). In 2007, quinolone resistance increased to the point that these agents can no longer be used to treat gonococcal infections in the United States. In 2011, increasing resistance to cephalosporins led to a change in recommended therapy for uncomplicated gonococcal infections (see Table 98-3). In particular, the current recommendation is a two-drug regimen of ceftriaxone 250 mg IM once *plus* azithromycin 1 g PO as a single dose.[5] Use of cefepime is discouraged owing to increasing resistance to this agent, and azithromycin is recommended over doxycycline. This combined regimen will also treat coinfection with *Chlamydia*.

Sexual partners (those within the previous 60 days or, if the last sexual encounter was more than 60 days before onset of symptoms, the last sexual partner) need referral for evaluation, testing, and treatment. Patients should be instructed to avoid sexual activity until therapy has been completed and until they and their

PO, orally.

partners are no longer symptomatic. Referral for HIV testing should be offered.

TRICHOMONIASIS

Trichomoniasis is caused by *Trichomonas vaginalis,* a flagellated protozoan. It is the most common nonviral STD in the world. As with other vaginal infections, up to 50% of infected women are asymptomatic. The most common presenting signs and symptoms include dysuria, vulvar irritation or itching, and vaginal discharge, often described as thin, malodorous, and yellow-green (Table 98-4). Affected patients also may report lower abdominal pain or discomfort and dyspareunia. Males are frequently asymptomatic and most often are seen as partners of infected women.

On physical examination, vaginal discharge is noted in up to 70% of patients, ranging in character from thin and scanty to the classic description of thick, frothy, and yellow. Vaginal pH is above 4.5. Punctate mucosal hemorrhages of the cervix ("strawberry cervix") have been described in 2 to 10% of patients. However, the history and physical examination findings are not sensitive or specific enough to make the diagnosis on clinical grounds alone, and testing is indicated.

The diagnosis most often is made by microscopic examination of a wet mount slide, but this method has a sensitivity of only 60 to 70%; sensitivity varies with the skill and thoroughness of the examiner and is optimized by examination of the slide soon after specimen collection. Culture is more sensitive than wet mount but is not widely performed, and culture results are not available in a timely manner for ED diagnosis and treatment. In men, urine sediment can be examined for trichomonads and also can be sent for culture. PCR assay is an alternate method for diagnosis of trichomoniasis. Several PCR primers have been studied, and each has demonstrated higher sensitivity than wet mount or culture.[11] PCR assay also has been found to be highly specific, exceeding 95%.[11] PCR testing is now available for combined point-of-care testing for *Trichomonas* along with gonorrhea and *Chlamydia.*[12]

Either of two single-dose treatments is recommended: metronidazole 2 g PO or tinidazole 2 g PO. Alternative therapy is metronidazole 500 mg PO twice daily for 7 days (see Table 98-4). Because these nitroimidazoles can cause a disulfiram-type reaction in persons who subsequently consume alcohol, patients taking these agents should be advised to avoid imbibing for 24 or 72 hours after the last dose of metronidazole or tinidazole, respectively. Topical metronidazole is available but is less efficacious than oral preparations for treatment of trichomoniasis and is not recommended for this use.

In pregnant women, trichomoniasis has been associated with premature rupture of membranes, premature labor, and low birth weight. Despite this association, treatment has not been shown to reduce these complications, although it may relieve local symptoms in the woman, may decrease the risk of infection of the newborn, and may decrease sexual transmission. Symptomatic pregnant women desiring treatment should be counseled on the risks and benefits. Metronidazole as a single 2-g dose is considered safe in any stage of pregnancy as studies have not shown an association between its use during pregnancy and mutagenic or teratogenic effects in the fetus.[13] Because its safety has not been well evaluated, tinidazole should not be used in pregnant patients.

Sexual partners of patients with *T. vaginalis* should be treated, and patients should be instructed to avoid sexual contact until they and their partners are clinically cured.

CANDIDIASIS

Vulvovaginal candidiasis most often is caused by *Candida albicans* but can be caused by other *Candida* species and other yeasts. It is estimated that 75% of women will have at least one episode of yeast vulvovaginitis in their lifetime, and 40 to 45% will have two or more episodes.

Common presenting signs and symptoms include vulvar itching or soreness, vaginal discharge, dyspareunia, and dysuria. Characteristic examination findings are vulvar erythema, vulvar edema or excoriation, and white curdlike vaginal discharge. Satellite lesions also may be seen. Vaginal pH is normal (less than 4.5) (see Table 98-4). Because none of these symptoms or signs is specific for candidiasis and the history and examination findings are relatively unreliable, diagnostic testing is indicated.

Diagnosis typically is based on wet-mount microscopy with use of potassium hydroxide (KOH) preparation or Gram's stain demonstrating yeast or pseudohyphae. The sensitivity of these tests ranges from 40 to 70%. Culture is more sensitive and is considered the gold standard diagnostic modality but is rarely performed, and 10 to 20% of asymptomatic women harbor *Candida* organisms and other yeasts in the vagina.

Multiple short-course topical preparations are available for treatment and effect an 80 to 95% cure rate in patients who complete therapy (see Table 98-4); many are available over the counter. Self-medication with over-the-counter preparations should be advised only for women who have been diagnosed previously with vulvovaginal candidiasis and experience recurrence of the same symptoms. Unnecessary or inappropriate use of over-the-counter preparations is common, can lead to contact or irritant vulvar dermatitis, and may delay treatment for other causes of vulvovaginitis. In addition, patients should be counseled that vaginal preparations are oil based, which may weaken latex condoms and diaphragms. Fluconazole, 150 mg in a single dose, is the only oral agent that is approved by the FDA for the treatment of candidiasis.

Candidal infections can be divided into complicated and uncomplicated types. Uncomplicated vaginitis is seen in 90% of patients. It is characterized by sporadic or infrequent episodes with mild to moderate symptoms caused by *C. albicans* in a normal host. It responds readily to short-course treatments. Complicated infections, associated with severe or recurrent symptoms (four or more episodes of vulvovaginal candidiasis each year), tend to occur in patients with complicating medical problems

www.ketabpezeshki.com 66485457-66963820

(e.g., immunosuppression, poorly controlled diabetes mellitus) and require longer courses of treatment (e.g., 7 to 14 days of topical therapy or a 150-mg oral dose of fluconazole given in three doses on days 1, 4, and 7).[5] Vulvovaginal candidiasis in HIV-positive patients is not considered complicated and should be treated as for uncomplicated vulvovaginal candidiasis.

Vulvovaginal candidiasis occurs frequently during pregnancy and may be more difficult to cure. Only topical azole therapies, applied for 7 days, are recommended for use during pregnancy; fluconazole is contraindicated.

Evidence to support treatment of asymptomatic sexual partners is lacking. In addition, no direct association has been found between yeast infection and other STDs, and no difference in yeast isolation rates has been observed in patients who have an STD and in those who do not.

BACTERIAL VAGINOSIS

Bacterial vaginosis occurs because of a shift in bacterial flora in the vagina, with replacement of the normal H_2O_2-producing *Lactobacillus* species with high concentrations of a polymicrobial group, including anaerobic bacteria (*Prevotella, Mobiluncus,* and *Bacteroides* species), *Gardnerella vaginalis,* and *Mycoplasma hominis,* and an attendant increase in the vaginal pH from 4.5 to as high as 7.0. Bacterial vaginosis is the most common cause of vaginal discharge and malodor (see Table 98-4). However, up to 50% of women with bacterial vaginosis are asymptomatic.

The most common manifestation is vaginal discharge, often with an offensive vaginal odor, which may be accentuated after coitus (the alkaline pH of semen induces a fishy odor, recognition of which constitutes a physiologic "whiff test"). Vaginal pruritus and irritation are not common complaints. On examination, a thin, white, homogeneous discharge is present.

Diagnosis can be made with the Amsel criteria (see Table 98-4).[5] Three of the four criteria must be present for diagnosis:

1. A thin, white homogeneous discharge that smoothly coats the vaginal walls.
2. Presence of clue cells in microscopic examination. (True clue cells are epithelial cells that are so heavily stippled with bacteria that the cell borders are obscured. Epithelial cells with few bacteria do not classify as clue cells.)
3. A pH of vaginal fluid greater than 4.5.
4. A fishy odor to the vaginal discharge before or after the addition of 10% KOH (whiff test).

Diagnosis also can be made with Gram staining to determine the relative concentrations of bacterial morphotypes (Nugent criteria). Culture isolation of *G. vaginalis* is not useful, because this organism can be cultured from vaginal specimens in more than 50% of healthy women and is therefore not specific. Several other available tests perform acceptably when compared with Gram staining, but these are usually not available in the emergency setting.

All symptomatic women should be treated. Bacterial vaginosis is associated with an increased risk of acute upper genital tract infection by the various organisms recognized as likely pathogens in such infections.[14] It is not known whether treatment of bacterial vaginosis reduces the risk of ascending infection, so screening for and treatment of bacterial vaginosis in asymptomatic women are not recommended.

Recommended treatment regimens for bacterial vaginosis include metronidazole 500 mg PO twice a day for 7 days, metronidazole gel 0.75% 5 g intravaginally every day for 5 days, and clindamycin cream 2% 5 g intravaginally at bedtime for 7 days. The vaginal cream is oil based and may weaken condoms and diaphragms; patients should be advised of this possibility. Alternative regimens include tinidazole 2 g PO once daily for 3 days, dinidazole 1 g PO once daily for 5 days, clindamycin 300 mg PO twice a day for 7 days, or clindamycin ovules 100 mg administered intravaginally once at bedtime for 3 days. Alternative regimens have lower efficacy for treatment of bacterial vaginosis. Patients taking tinidazole and metronidazole should be advised to avoid alcohol for up to several days after treatment to avoid the disulfiram-like reaction that may be seen when these agents are taken. Treatment of sexual partners does not affect response to therapy or recurrence rates and is therefore not recommended.

All pregnant women with symptoms should be treated. Bacterial vaginosis during pregnancy is associated with premature rupture of membranes and preterm labor, preterm birth, and postpartum endometritis. Studies have not consistently demonstrated a benefit of treatment for asymptomatic pregnant patients, but treatment may be considered in women with a previous preterm birth or those who are at high risk for preterm birth.[15] Recommended treatment regimens in pregnancy include metronidazole 500 mg PO twice a day for 7 days, metronidazole 250 mg PO three times a day for 7 days, and clindamycin 300 mg PO twice a day for 7 days. Topical agents are not recommended for use during pregnancy.[5] Metronidazole use during pregnancy has no demonstrated association with teratogenic or mutagenic effects in newborns.

OTHER CAUSES OF GENITAL DISCOMFORT

Many other conditions manifest with vulvovaginal itching or discharge. Considerations in the differential diagnosis include the sexually transmitted and vaginal infections discussed previously, as well as allergic or chemical vaginitis, atrophic vaginitis, scabies, pediculosis pubis (genital lice), and vaginal foreign bodies.

Chemical vaginitis most commonly is associated with the use of douches, scented soaps, or feminine hygiene products. In addition, some women with a latex allergy may report vaginal itching and discomfort after intercourse with a partner who uses latex condoms. Diagnosis is by history, and discontinuing use of the offending agent usually is sufficient treatment.

Atrophic vaginitis occurs when levels of circulating estrogens decrease after menopause. Patients may report increased vaginal itching, vulvar discomfort, and dyspareunia. Other sources of discomfort, such as *Candida* infection, should be ruled out, because relative lack of estrogen predisposes affected women to vaginal and vulvar infections. Treatment typically consists of topical estrogen creams.

The mite *Sarcoptes scabiei* causes scabies infestation, and any part of the body may be affected. Transmission is by skin contact. The main symptom is pruritus, which is caused by a hypersensitivity reaction to mite excrement. The diagnosis is made clinically by identification of characteristic silvery lines seen in the skin where the mites have burrowed. Papules or nodules also may be noted, especially in the genital area. Scrapings viewed under the light microscope contain mites, confirming the diagnosis. Topical treatment for scabies is permethrin cream (preferred agent), lindane, or benzyl benzoate. In infants, permethrin 5% cream is the only indicated therapy. This agent can also be used in children, who may also be treated with benzyl benzoate 12.5%. Ivermectin, the only oral treatment for scabies, is more effective than topical permethrin.

Phthirus pubis is a crab louse transmitted by close body contact. Adult lice infest pubic hair, body hair, and occasionally the eyebrows and eyelashes. Eggs (nits) adhere to the hairs. The main symptom is pruritus caused by hypersensitivity reaction to the feeding lice. Diagnosis is based on finding adult lice or eggs. Treatment includes pyrethrin shampoos and permethrin 1% rinses (available over the counter), permethrin 5%, malathion, lindane, and ivermectin topical.

PELVIC INFLAMMATORY DISEASE

Perspective

PID is a spectrum of disorders of the female upper genital tract, including any combination of endometritis, salpingitis, peritonitis, and tubo-ovarian abscess. Approximately 750,000 cases of PID are diagnosed annually in the United States.[1] The serious complications of PID (infertility, ectopic pregnancy, and chronic pelvic pain) account for a significant proportion of non-HIV STD-related morbidity in the United States and affect approximately 25% of diagnosed patients.[16] PID is reported to be the most common serious infection in women of reproductive age and causes approximately 30% of infertility cases, 50% of ectopic pregnancies, and many cases of chronic pelvic pain.[16]

Principles of Disease

PID is an ascending infection, with the infecting microorganisms spreading from the cervix and vagina to the upper portions of the female genital tract. Although the most commonly implicated organisms are *C. trachomatis* and *N. gonorrhoeae,* the cause of PID often is polymicrobial, and various microorganisms have been recovered in patients with acute PID, including genital mycoplasmas and anaerobic and aerobic bacteria from endogenous vaginal flora such as *Prevotella* species, peptostreptococci, *G. vaginalis, E. coli, Haemophilus influenzae,* and aerobic streptococci. Although organisms that are associated with sexual transmission are those most commonly found with PID, this infection can be caused by nonsexually acquired organisms. Patients diagnosed with PID should be counseled that the infection can be acquired nonsexually and that the diagnosis does not imply that either sexual partner may have had sexual encounters outside the relationship.

Risk factors for the development of PID include young age, multiple sexual partners, cigarette smoking, and menses. Intrauterine contraceptive devices (IUDs) have previously been implicated as a major risk factor for PID; however, IUDs increase the risk of PID only in the 3 weeks after insertion. It should be noted that nearly half of patients with PID do not have identifiable risk factors; a lack of risk factors does not rule out the infection.

Clinical Features

Owing to the wide range of presenting signs and symptoms, acute PID is challenging to diagnose. The most common presenting symptom is lower abdominal pain. Other signs and symptoms include dyspareunia, abnormal bleeding, abnormal cervical or vaginal discharge, abdominal pain, and fever. Physical examination may reveal a fever, abdominal pain, and lower abdominal tenderness, cervical motion, or adnexal tenderness (unilateral or bilateral) on bimanual palpation.

Studies show that many women with PID demonstrate mild, vague, or subtle symptoms, often not recognized as manifestations of PID by either the patient or her physician. Unrecognized PID probably is as common as, if not more common than, clinically apparent disease, and it is estimated that up to two thirds of cases may go unrecognized. *Silent* or *atypical PID* is a term that has been used to describe the underlying disorder in women with documented tubal infertility who have no history of being diagnosed with PID despite confirmed chronic inflammatory residua.

Patients also can report right upper quadrant pain and tenderness, which may be preceded or accompanied by the signs and symptoms of PID. This syndrome, known as *perihepatitis* or *Fitz-Hugh–Curtis syndrome,* has been associated with both gonococcal and chlamydial salpingitis. Transaminases will be normal. Fitz-Hugh–Curtis syndrome may develop in up to 10% of patients with PID, depending on the organisms implicated as the cause.[5]

When compared with laparoscopy as the gold standard for making the diagnosis of PID, the clinical examination has a sensitivity ranging from 65 to 90%.[17] The positive predictive value of the clinical diagnosis depends on the epidemiologic milieu in which the diagnosis is made. There is no single historical, physical, or laboratory finding, or combination of these that is adequately sensitive or specific to permit a definitive diagnosis of PID. With that in mind, and because of the difficulty in making the diagnosis and the serious long-term sequelae of PID, current recommendations call for a low threshold to both consider this clinical entity and to institute appropriate treatment in patients who may have PID.

The CDC recommends empirical treatment for PID in sexually active young women experiencing pelvic or lower abdominal pain if any one of the following minimum criteria is present without other identifiable causes:

- Cervical motion tenderness
- Adnexal tenderness
- Uterine tenderness

Controversy also surrounds what constitutes cervical motion tenderness. Although the traditional "chandelier sign" (pain so severe the patient ends up "swinging from a chandelier") of severe tenderness has been taught as the criterion standard, the patient herself should be questioned about her degree of pain. If it is more than the usual discomfort experienced by the patient during a pelvic examination, this should be considered positive evidence for cervical motion tenderness.

Other criteria that support but are not necessary for the diagnosis of PID include the following:

- Oral temperature greater than 101° F (38.3° C)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of WBCs on wet mount preparations of vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein level
- Laboratory documentation of cervical infection with *N. gonorrhoeae* or *Chlamydia*

As more criteria for diagnosis are met, the specificity increases but the sensitivity decreases. The absence of either mucopurulent cervical discharge or WBCs on wet mount preparations makes the diagnosis of PID unlikely; in such cases, other causes of abdominal pain should be sought. Ultrasonography also may be useful in the diagnosis of PID, especially in identifying tubo-ovarian abscess or pyosalpinx. If the diagnosis is unclear, particularly in patients with fever and peritoneal signs, further testing is indicated. In these cases, computed tomography may rule out other causes of peritoneal clinical findings, such as appendicitis or diverticulitis, and in some cases laparoscopy may be necessary to determine the cause of the patient's illness.

Differential Diagnosis

The differential diagnosis of lower abdominal pain in young women is broad in scope. Other common diagnostic considerations include ectopic pregnancy, acute appendicitis, endometriosis, ovarian cysts, and functional abdominal pain.

Management

The goal of treatment in PID is to prevent the chronic sequelae of infection. Treatment regimens should provide broad-spectrum coverage against likely pathogens, including *N. gonorrhoeae, Chlamydia,* anaerobes, gram-negative bacteria, and streptococci. Although endocervical testing is recommended in these patients, negative results do not preclude upper tract infection.

Table 98-5 Treatment for Pelvic Inflammatory Disease

REGIMEN A	REGIMEN B	REGIMEN C
Inpatient		
Cefoxitin 2 g IV q6h *or* Cefotetan 2 g IV q12h *plus* Doxycycline 100 mg PO or IV q12h	Clindamycin 900 mg IV q8h *plus* Gentamicin 2 mg/kg IV or IM load, *then* 1.5 mg/kg IV or IM q8h *or* single daily dose (3-5 mg/kg) can be substituted	
Continue until at least 48 hours after improvement	Continue until at least 48 hours after improvement	
Continue doxycycline 100 mg PO bid for 10-14 days total	Continue doxycycline 100 mg PO bid for 10-14 days total	
	Continue clindamycin 450 mg PO q6h or change to doxycycline	
Outpatient		
Ceftriaxone 250 mg IM once *plus* Doxycycline 100 mg PO bid × 14 days *with or without* Metronidazole 500 mg PO bid × 14 days	Cefoxitin 2 g IM *plus* Probenecid 1 g PO once *plus* Doxycycline 100 mg PO bid × 14 days *with or without* Metronidazole 500 mg PO bid × 14 days	Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime) *plus* Doxycycline 100 mg PO bid for 14 days *with or without* Metronidazole 500 mg PO bid × 14 days

IM, intramuscularly; *IV,* intravenously; *PO,* orally.

Delaying treatment may increase the risk of developing long-term sequelae.

In patients with mild-to-moderate disease, no studies have clearly demonstrated differences in efficacy of parenteral versus oral therapy, or of inpatient versus outpatient treatment. The decision to hospitalize a patient should be based on the clinical presentation and other comorbid or complicating factors. The CDC suggests that any of the following criteria constitutes grounds for hospitalization:

- Surgical emergencies such as appendicitis cannot be excluded.
- The patient is pregnant.
- The patient does not respond clinically to oral antimicrobial therapy.
- The patient is unable to follow or tolerate outpatient oral regimens.
- The patient has a severe illness, nausea and vomiting, or high fever.
- The patient has a tubo-ovarian abscess.

Parenteral and oral regimens are listed in Table 98-5. If outpatient treatment is chosen, patients must be reevaluated within 24 to 48 hours to assess response to oral therapy. If there is no response, the patient should be hospitalized for parenteral antibiotic therapy and confirmation of the diagnosis.

Patients should demonstrate significant clinical improvement, such as defervescence, decreased abdominal tenderness, and reduction in uterine, adnexal, and cervical motion tenderness, within 3 days of initiation of therapy. Sexual partners of patients diagnosed with PID should be evaluated and empirically treated for gonorrhea and chlamydial infection. Patients should be counseled to avoid sexual activity until both they and their partners have completed treatment. It is recommended by some specialists that patients with documented gonorrhea and chlamydial infection be reevaluated for test of cure in 4 to 6 weeks after completion of therapy, although this practice is not universal.

KEY CONCEPTS

- Patients with ulcerative genital lesions should be considered to have an STD and should be tested and treated accordingly.
- Patients with suspected gonorrheal infection also should be treated for chlamydial infection.
- Sexually active women with adnexal or cervical motion tenderness should be treated for PID.
- A single dose of azithromycin is inadequate to treat upper female genital tract infection; patients require a 2-week course of antibiotics.
- Asymptomatic women with clue cells on wet mount preparations should not be treated for bacterial vaginosis.
- Pregnant women with bacterial vaginosis should not be treated if they are asymptomatic unless they are at risk for preterm labor or premature birth (i.e., if they have a history of preterm labor, miscarriage, or premature rupture of membranes).
- Patients with sexually transmitted infections are at risk for HIV infection and should be either tested in the ED or referred for HIV testing.

Chapter 99

Selected Urologic Problems

Kevin M. Ban andJoshua S. Easter

URINARY TRACT INFECTIONS

Perspective

Background

Urinary tract infection (UTI) describes an inflammatory response of urothelium to microorganisms in the urinary tract, resulting in clinical symptoms including dysuria, frequency, urgency, hematuria, and suprapubic or costovertebral angle discomfort self-reported by the patient or elicited on physical examination. This term does not differentiate between upper and lower tract infections. Traditionally the emphasis has been on distinguishing lower tract from upper tract infections. Although this distinction may seem sensible from an anatomic perspective, it often does not provide additional information for making important management and disposition decisions. *Bacteriuria* is the presence of bacteria in the urine but is not considered to represent a UTI in the absence of clinical manifestations. Bacteriuria accompanied by symptoms should be treated, whereas bacteriuria in the absence of symptoms should be treated only in select patients (e.g., pregnant women, immunosuppressed patients).[1]

It is more useful to designate UTIs as being either uncomplicated or complicated, rather than as lower or upper tract infections. An *uncomplicated* infection is one involving a structurally and functionally normal urinary tract. The causative pathogen generally can be eradicated with a short course of standard antibiotics.[2] This type of infection usually occurs in nonpregnant, sexually active, young women who have no evidence of an obstructive process. *Complicated* infection is that associated with underlying neurologic, structural, or medical problems, all of which may reduce the efficacy of standard antimicrobial therapy. These types of infections often require a prolonged course of antibiotic therapy and a more in-depth approach to testing and anatomic evaluation.

Urethritis refers to the inflammation of the urethra secondary to either an infection or trauma. Frequently, urethritis may be a manifestation of a sexually transmitted disease (STD), such as gonococcal urethritis in *Neisseria gonorrhoeae* infection, but may occur in other clinical scenarios as well. *Cystitis* generally refers to inflammation of the bladder resulting in increased urinary frequency, urgency, dysuria, and suprapubic pain. Cystitis can be separated into bacterial and nonbacterial (e.g., radiation) etiologic categories. Acute pyelonephritis is a UTI of the renal parenchyma and collecting system manifesting with the clinical syndrome of fever, chills, and flank pain. Management and disposition of patients with acute pyelonephritis depend on whether the infection is simple or complicated.

Epidemiology

UTI is a problem that affects all age groups.[3,4] It is considered the most frequently occurring bacterial infection, accounting for 7 to 8 million annual outpatient visits, 1 million annual emergency department (ED) visits, 100,000 annual hospitalizations, and more than one third of all hospital-acquired infections.[1,5] These statistics notwithstanding, gauging the actual extent of the disorder is very difficult because it is not a reportable disease in the United States and the definition of a UTI is not exact.

Women have a 50% chance of experiencing a UTI during their lifetime.[2] The annual incidence of UTIs is 2 to 4% among young, sexually active women and gradually increases to 5 to 10% by the age of 70 years and to approximately 50% by the age of 80 years.

UTIs account for 5 to 14% of pediatric ED visits in the United States. UTI is more common in boys during the neonatal period but becomes more common in girls during infancy and thereafter.[6] When a UTI is seen in preschool boys, it is almost always associated with congenital anomalies of the urinary tract. The overall risk for all children with unexplained fever having a UTI is 7 to 9%.[7]

UTIs in adult men are uncommon unless cystoscopy or catheterization has been performed. The prevalence is less than 1% from childhood through middle age but increases to 1 to 3% by the age of 65 years and to 10% by the age of 80 years. Among institutionalized men and women, prevalence rates for bacteriuria and UTI are increased to approximately 25% and 40%, respectively.[3] UTIs associated with presence of an indwelling catheter constitute the most common nosocomial infection in the United States, accounting for more than 1 million cases annually.[8]

Principles of Disease

Physiology

The urine is sterile along the entire urinary tract from the glomerulus to the external sphincter in men and to the bladder neck in women. The urinary tract maintains its sterility by means of various defenses. A major mechanism is complete emptying. Free, unobstructed flow of urine within the kidney and down the ureter, coupled with complete evacuation of the bladder, is essential. Abnormal anatomy or physiology or the presence of a foreign body may compromise host defense mechanisms and predispose the patient to infection.[5]

In men the distal end of the urethra is inhabited by staphylococci, streptococci, and diphtheroid organisms. Nevertheless, men

www.ketabpezeshki.com 66485457-66963820

generally do not become infected without an underlying obstruction of normal urinary flow.

In women the urethra is short and opens close to the vulvar and perirectal areas. The organisms that cause UTI in women usually arise from the fecal reservoir and initially colonize the vaginal introitus and periurethral area.[4] These factors contribute in part to the much higher incidence of UTI in women.

Pathophysiology

Bacteria most often enter the urinary tract by ascent through the urethra and into the collecting system. Infrequently, bacterial infection of the urinary tract arises from hematogenous or lymphatic sources. This is the usual pathologic mechanism in debilitated and chronically ill patients who are immunosuppressed. Organisms from distal foci of infection such as endocarditis or soft tissue sources may make their way through lymphatic or hematogenous channels, resulting in a UTI. In these patients, it is important to identify and treat the primary source of infection.

Numerous abnormalities of the urinary tract interfere with its innate ability to resist infection. Obstruction from any cause, with resultant stasis of urine, is the major causative factor. Any obstruction or impediment to the free flow of urine or complete bladder emptying results in an increased incidence of infection. Urinary calculi may cause obstruction and increased susceptibility to the development of UTI. It is crucial that obstruction in the setting of infection be relieved promptly.

Vesicoureteral reflux in children plays an important role in the pathogenesis of UTIs, particularly upper tract infections. Reflux caused by congenital abnormalities or by bladder overdistention (as seen in advanced prostatic hypertrophy) also predisposes affected patients to infection. Subgroups of patients who are more susceptible than the normal population to UTIs include diabetic patients, pregnant women, the elderly, patients with spinal cord injury and indwelling urinary catheters, patients with multiple sclerosis, and those with immunodeficiency disorders such as human immunodeficiency virus (HIV) infection.[5]

In young men, asymptomatic bacteriuria is rare and may signify urinary tract disease. UTIs in men generally begin to appear at 50 years of age (concomitant with the onset of prostatic hypertrophy) and slowly increase in incidence.[9] The occurrence of UTIs in men of any age warrants referral to a urologist for further evaluation.

Bacteriology

The organisms that cause UTIs generally come from enteric flora colonizing the perineum and urethra. *Escherichia coli* is the dominant pathogen in more than 80% of first infections in women, men, and children, as well as in 50% of nosocomial UTIs.[10] *Staphylococcus saprophyticus,* a coagulase-negative gram-positive organism, is the second most common pathogen in UTI and accounts for approximately 11% of cases.[5] This species is present in normal skin flora, including the perineal area, but only in low numbers, and it does not appear to be of fecal origin. Occasionally, it is falsely identified as *Staphylococcus albus* or *Staphylococcus epidermidis.* Other, less common bacteria that may be responsible for infection include *Proteus, Klebsiella,* and *Enterobacter.*[5] Unusual microorganisms may be found in institutionalized or hospitalized populations and with complicated UTIs. Such settings and conditions predispose the patient to alterations in the normal gastrointestinal (GI) flora, leading to complex UTIs. The uropathogens in these patients include more resistant strains of *Escherichia, Klebsiella, Proteus,* and *Enterobacter,* as well as *Pseudomonas, Enterococcus, Staphylococcus, Providencia, Serratia, Morganella, Citrobacter, Salmonella, Shigella, Haemophilus, Mycobacterium tuberculosis,* and fungi. Although not necessary with uncomplicated UTIs, urine culture and sensitivity testing are recommended for all patients with complicated UTIs. Antibiotic therapy based on the most likely pathogen should be initiated immediately.

Uropathogenic organisms may elaborate various factors that affect their virulence, including aerobactin, hemolysins, and fimbriae (pili). Fimbriae, also called *adhesions,* are proteinaceous structures that can attach to specialized receptor sites on host cells. Attachment of bacteria to vaginal and uroepithelial cells ultimately leads to a higher incidence of UTI.[11]

Clinical Features

Signs and Symptoms

UTI is suspected in adolescents and adults on the basis of clinical findings, including dysuria, frequency, urgency, and hematuria in the setting of suprapubic or costovertebral angle (CVA) discomfort. Symptoms and signs vary with age. In infants, initial manifestations may include irritability, fever, vomiting, diarrhea, and failure to thrive. Preschool children with UTI have vomiting, diarrhea, generalized abdominal pain, and febrile seizures. History of fever alone is not an adequate indicator of severity of infection in children because it may be historically absent in pediatric patients subsequently found to have significant renal scarring.[12]

In general, clinical signs and symptoms associated with *lower* UTIs are localized to the genitourinary system and include urgency, dysuria, frequency, and suprapubic pain. In addition to these problems, a patient with an *upper* UTI may have back and flank pain as well as constitutional symptoms and signs such as fever, nausea, vomiting, and malaise.

As discussed previously, it is more important to determine if the infection is simple or complex. Simple, uncomplicated infections do not require urine culture, may be treated on an outpatient basis, and may not always necessitate urinalysis when thought to represent isolated cystitis.[10] Complicated infections require urine culture with antibiotic sensitivity and also may necessitate inpatient therapy with further diagnostic evaluation.[13] Distinction between upper and lower tract infections becomes important for understanding the differences in pathology and the pharmacokinetics of antibiotic delivery. Infection of the bladder generally involves only the superficial mucosa, and high urinary concentrations of antibiotics can easily be achieved with a short course of antibiotic therapy. The kidney, by contrast, tends to become infected in the medullary tissue, where achieving therapeutic concentrations of antimicrobial agents is far more difficult. As a result, parenteral antibiotics and longer courses of therapy are needed.

Men who report dysuria must be evaluated for the presence of urethral discharge before urinalysis is performed. In these patients, in whom the diagnosis of UTI is rare, the most likely causative disorder is an STD such as gonococcal or nongonococcal urethritis. If the patient has purulent urethral discharge, he should undergo testing for *Chlamydia trachomatis, N. gonorrhoeae,* and syphilis, as well as empirical treatment for STDs. If the patient does not have urethral discharge and complains predominantly of dysuria, frequency, urgency, and suprapubic or CVA discomfort, a urinalysis with culture should be performed. Male patients who have bacteriuria in the absence of clinical signs of urethritis or prostatitis should be considered to have a complicated UTI and should be treated with antibiotic therapy and undergo urologic follow-up for further evaluation.

Diagnostic Strategies

Laboratory Tests

Urine Collection Methods. The diagnostic value of microscopic examination depends on the quality of the specimen obtained. In neonates and children younger than 6 months, urethral

www.ketabpezeshki.com 66485457-66963820

catheterization is the preferred method of urine collection. Aseptic technique ensures a low risk of introducing bacteria. Before catheterization is attempted in these younger patients, an ultrasound or bladder scanner can be used to confirm the presence of urine in the bladder. Suprapubic bladder aspiration is a reliable method if urine is available to be withdrawn, but it is less commonly used owing to the invasiveness of the procedure. For patients 12 months or younger, ultrasound-guided suprapubic bladder aspiration is a useful method and carries an incidence of adverse effects similar to that of urethral catheterization. Plastic bag collection is a reasonably reliable method, but the perineum (in girls) and the glans (in boys) should be properly cleansed before application of the bag. It is the least invasive method but is useful only if culture results are negative, because of high associated contamination rates. A clean-catch urine specimen is preferred in cooperative and continent male patients.

In older children, a sterile midstream urine sample can be collected from boys. In girls, if the voided specimen is free of cellular elements (epithelial cells), it is acceptable for analysis. Catheterization often is a traumatic experience for children and one that invades their sense of privacy. An alternative approach to catheterization in a young girl with classic symptoms of UTI who has epithelial cells in the urine suggesting contamination is to evaluate the urine for other signs of infection. If the urine contains bacteria, red blood cells (RBCs), and white blood cells (WBCs) and is either nitrite or leukocyte esterase positive, the most likely cause of the symptoms is an uncomplicated UTI, for which antibiotic therapy and referral for follow-up care with the child's pediatrician are indicated. If the clinical picture remains unclear and a definitive diagnosis is mandatory, straight catheterization is performed after examination of the child's bladder with an ED ultrasound machine has confirmed the presence of urine.

Recommendations regarding urine collection methods in women vary widely. Midstream-voided specimens rarely escape perineal contamination, because for most adult women, adequate preparatory self-cleansing of the perineal area is difficult to achieve. It has been shown that in up to 50% of women with sterile bladder urine, a midstream clean-catch specimen grows 1000 to 100,000 bacterial colony-forming units (CFUs) per milliliter. This finding assumes major significance in the ED evaluation, in which accurate, initial supportive evidence for the diagnosis of UTI is crucial.

Sterile catheterization is the quickest and most accurate method of obtaining a urine specimen from an adult woman and may be the best solution for achieving a reliable urinalysis if the patient is actively menstruating. It is safe and relatively atraumatic and carries a remarkably low risk of infection. This risk increases if the patient is pregnant, elderly, or debilitated. If the clinician decides against catheterization, a clean-catch, midstream urine specimen should be sought. A predominance of epithelial cells suggests that the specimen is contaminated. The lower the ratio of leukocytes to vaginal epithelial cells, the more likely it is that the leukocytes are vaginal contaminants.

In men the specimen is not affected significantly by lack of cleansing or by the timing of specimen collection. Therefore it is not appropriate to catheterize an adolescent or adult man simply for the purpose of collecting a urine specimen.

Urinalysis. Urine cultures constitute a majority of cultures performed by microbiology laboratories, and various screening tests have been developed for the purpose of reducing this burden and its attendant costs. The goal of urine screening tests is reliable selection of specimens that will provide negative cultures. This allows the laboratory to focus more appropriately on higher-yield studies.

The most commonly used screening tests measure urinary leukocyte esterase and nitrite. Leukocyte esterase is an enzyme found in neutrophils, and nitrite is produced from urinary nitrate by nitrate reductase, which is present in gram-negative bacteria. Both can be detected by a color change on dipstick testing. The two tests often are combined to improve overall accuracy. Indirect urine dipstick tests for pyuria or bacteriuria are inexpensive and easy to perform and may aid in establishing the diagnosis of UTI. They should be used with caution, however, because they can be less sensitive than microscopic examination of urine (urinalysis). Urine dipstick testing for leukocyte esterase has shown a sensitivity of 75 to 96% in detecting pyuria associated with UTI. By contrast, a meta-analysis of screening tests for UTI in children has demonstrated that dipstick testing for leukocyte esterase and nitrite may be equivalent to microscopic urinalysis for detection of UTI.

Symptomatic patients who have normal host defenses and demonstrate a positive result on leukocyte esterase testing (in the absence of other indications for urine culture) can be treated empirically without culture. In symptomatic patients, a negative result on tests for both leukocyte esterase and nitrite should be followed by urine microscopy. In adults, urine culture should be performed only if findings on the microscopic analysis also are negative or if the patient is at risk for bacteremia.

Urine Microscopy. Urine microscopy is another commonly used method of providing rapid results, thereby reducing the number of urine cultures performed. Up to 96% of infected urine specimens contain 10 or more WBCs per cubic millimeter when counted by a hemocytometer. Various counting chamber methods detect pyuria with an accuracy approaching that of the hemocytometer. Unfortunately, these tests are not widely available, so direct microscopy commonly is used.

The accuracy of direct microscopy is compromised by a lack of standardization of the technique. Common sources of variability include specimen collection and transport, centrifugation speed and duration, decanting and resuspension techniques, staining, and the threshold used for significant numbers of WBCs or bacteria. One method, the slide centrifuge test, avoids many of these sources of error, and high sensitivity and specificity have been reported.

Although no accepted level of pyuria is diagnostic of UTI, on careful quantitation with a hemocytometer chamber, pyuria will be found in nearly all cases of acute UTI caused by coliforms. In patients with a low-count coliform infection, those with fewer than 8 WBCs/mm^3 of urine will have no demonstrable infection. In patients with more than 8 WBCs/mm^3, 85% will have documented infection (by the presence of coliforms, staphylococci, or chlamydiae). Despite these controversies and limitations, microscopic examination of urine to identify bacteria remains the most readily available and reliable test for a presumptive diagnosis of UTI in most patient populations.[14] Any analysis of a urine sample must be performed immediately after collection. Urine specimens that are allowed to sit for longer than 2 hours become alkaline, with subsequent dissolution of the cellular elements and multiplication of bacteria, thus providing the clinician with markedly unreliable results.[15]

Urine Culture. Definitive diagnosis of UTI is based on isolation of significant numbers of bacteria on urine culture. Traditionally, 10^5 CFUs/mL has been used as the statistically significant number for the presence of UTI. However, use of an absolute number is fraught with limitations. The presence of 10^5 CFUs/mL of bacteria in cultures from urine is associated with a 95% likelihood of infection, whereas 10^4 CFUs/mL is associated with a 50% likelihood of infection. It makes best clinical sense to put these results in clinical context regarding the presence of symptoms suggestive of a UTI. The symptom complex of dysuria, frequency, urgency, and suprapubic pain may be caused by a wide variety of infectious organisms in numbers far less than the traditional 10^5 CFUs/mL. In addition, these same symptoms may represent a significant upper tract infection or may be caused by urethritis.

www.ketabpezeshki.com 66485457-66963820

Box 99-1 Patient Groups in Which Urine Culture Is Indicated

- Children
- Adult men
- Immunocompromised patients
- Patients with "treatment failure" (i.e., with persistent urinary symptoms despite recently completed course of antibiotics)
- Patients with duration of symptoms more than 4 to 6 days
- Elderly patients at risk for bacteremia
- Ill-appearing patients with signs and symptoms suggestive of pyelonephritis or bacteremia
- Pregnant women
- Patients with known chronic or recurrent renal infection
- Patients with known anatomic urologic abnormalities
- Patients in whom urinary tract obstruction is suspected (e.g., stones, benign prostatic hypertrophy)
- Patients with serious medical diseases, including diabetes mellitus, sickle cell anemia, cancer, and other debilitating diseases
- Patients with alcoholism or drug dependence
- Recently hospitalized patients
- Patients taking antibiotics
- Patients who recently have undergone urinary tract instrumentation (e.g., cystoscopy, catheterization)

The presence of bacteria on culture in the absence of clinical manifestations does not always indicate infection. Women often carry large numbers of pathogenic bacteria on the perineum, and uncircumcised men may harbor large quantities of uropathogenic bacteria on the foreskin. The presence of bacteria in these regions may contaminate otherwise sterile bladder urine during collection.

The decision to perform a urine culture should be assessed for its relevance to patient care. Patients with frequency, dysuria, urgency, and suprapubic pain should be treated on the basis of symptoms if the infection is thought to be simple, and a urine culture is not required to guide therapy. For women who have host factors (e.g., structural abnormalities) or comorbid conditions (e.g., compromised immune status, pregnancy) necessitating definitive identification of the organism by culture, both urinalysis and culture are necessary. In general, the list of indications for urine culture (Box 99-1) defines high-risk groups. In vitro sensitivity testing contributes little to the general management of patients with uncomplicated UTI. Correlation between the therapeutic response and in vitro testing results often is poor. Culture also represents an additional cost with minimal contribution to the therapeutic plan for most outpatients.

Imaging. The majority of patients with acute cystitis or pyelonephritis do not need emergency imaging of the urinary tract. In certain clinical settings, however, emergency imaging is indicated. Patients with either unusually severe signs and symptoms or an atypical clinical presentation are candidates for genitourinary imaging. For example, a patient with the classic signs and symptoms of pyelonephritis but unremarkable urinalysis findings may have an obstructive process that has prevented the leukocytes and bacteria from reaching the bladder. Another example is that of a patient with a known history of UTI, currently receiving antibiotic therapy, who has persistent fever, chills, and general toxicity. Perhaps one of the most sensitive predictors of a complicated infection (e.g., abscess) is the persistence of fever beyond 72 hours after the institution of antimicrobial therapy. Pyelonephritis with obstruction from any cause can rapidly lead to abscess formation with resultant deterioration of renal function and sepsis. Emergency imaging is indicated to rule out this condition or to identify a suspected renal stone serving as a nidus for infection.

First episodes of UTI in selected patients, such as children younger than 4 years, generally require evaluation after resolution of the UTI. These patients are more likely than those in the general pediatric population to have structural anomalies and, if untreated, are at increased risk for recurrent UTI or for the development of complications such as hydronephrosis, renal scarring, and ultimately renal failure. The female patient with multiple episodes of complex infection, the patient with diminishing renal function, and the patient with renal colic and a possible obstructing stone, which progresses to sepsis, all require imaging.

Several imaging studies may be useful in these patients. Historically, intravenous or excretory urography—typically, intravenous pyelography (IVP)—was used because such studies provide both structural and functional information about the upper urinary tract. Recent work has focused on obtaining this information through safer, less invasive, and less costly methods.[16] Ultrasonography compares favorably with IVP but is inferior to computed tomography (CT).[17] Radionuclide cystograms compare favorably with voiding cystourethrograms in the diagnosis of vesicoureteral reflux and give less ionizing radiation to the gonads by a factor of 50 to 100. Voiding cystourethrography is the traditional method for initial evaluation of the genitourinary tract. CT scan is exceptional for diagnosing upper tract complications such as various degrees of pyelonephritis, abscesses, pyonephrosis, granulomatous infections, and infected cysts. As with IVP, its disadvantages include higher cost, radiation exposure, and potential for contrast-induced reactions.

Ultrasonography. Ultrasonography is useful in the evaluation of patients with potential urinary obstruction. It is a sensitive tool for detecting intrarenal and perinephric abscess and the presence of hydroureter and hydronephrosis. It is less accurate in determining the presence of a partially obstructing ureteral stone. Ultrasound examination also can detect the presence of pyelonephritis and congenital anomalies. Regardless of patient age group, this procedure is relatively inexpensive and avoids the hazards of contrast and radiation exposure.

Intravenous Pyelography. IVP, previously considered one of the mainstays in the evaluation of the genitourinary tract, has been nearly replaced by helical CT scanning and ultrasonography. IVP has higher sensitivity and specificity for determining the presence of obstruction than ultrasound examination but is inferior to CT scanning, and it is not sensitive for detecting the presence of pyelonephritis and renal abscess.[18]

Radionuclide Scans. Radionuclide scans also are gaining popularity for the early evaluation of UTI. A dimercaptosuccinic acid scan is the most sensitive method of identifying pyelonephritis and is the imaging study of choice in infant girls with UTI and fever.

Computed Tomography of the Abdomen. A contrast-enhanced CT scan of the abdomen is perhaps the best test for assessing the kidneys, ureters, and bladder. It has the highest sensitivity for detecting abscess, obstruction, and acute inflammation.[17] Its disadvantages include cost, radiation exposure, and potential for contrast-induced reactions and radiocontrast agent–induced acute kidney injury, which occurs infrequently in patients with a serum creatinine less than 1.5 mg/dL and can be further avoided by intravenous hydration with normal saline. CT without contrast can be performed in patients with renal insufficiency and is the preferred study in patients with clinical concern for urolithiasis.

Complicated Urinary Tract Infection in High-Risk Populations

Pregnancy

UTI during pregnancy represents a special situation. The incidence of UTI in pregnancy is approximately 2 to 7%.[19] Maternal complications include acute pyelonephritis, increased incidence of

www.ketabpezeshki.com 66485457-66963820

postpartum chronic pyelonephritis, preterm delivery, and low newborn birth weight. The physiologic changes that occur within the urinary tract of pregnant women include ureteral and renal pelvis dilation, as well as reduced peristalsis throughout the collecting system. During the last trimester, minimal ureteral contractions occur in many patients.

Unlike bacteriuria in nonpregnant females, bacteriuria in pregnant women, even if they are asymptomatic, should be treated. Complications that may result from untreated bacteriuria in pregnancy include premature labor, perinatal mortality, maternal anemia, and maternal pyelonephritis.

Reasonable antibiotic choices include amoxicillin, cephalexin, and nitrofurantoin. Trimethoprim-sulfamethoxazole (TMP-SMX) may be used before the third trimester. Single-dose therapy is not recommended, because these are not considered simple infections. Hospital admission should be considered in patients who are in their last trimester, who appear ill, or who have evidence of pyelonephritis and would benefit from treatment with parenteral antibiotics and intravenous fluids. Although pregnant patients with UTI are being treated on an outpatient basis more frequently than in the past, conservative treatment and close follow-up are warranted.

Diabetes and Sickle Cell Disease

Diabetic patients with bacteriuria also have an increased risk for the development of pyelonephritis, but treatment of asymptomatic bacteriuria has not been proved to be beneficial and should not be standard therapy at this time.[20] Papillary necrosis, perinephric and renal abscess formation, and emphysematous cystitis represent grave complications for this patient group. Manifestations of these complications may include altered vital signs, systemic signs and symptoms such as nausea and vomiting with dehydration, and a toxic appearance suggesting bacteremia and sepsis. These patients require aggressive fluid resuscitation, intravenous antibiotics, and a thorough diagnostic investigation including CT scanning.

Patients with sickle cell anemia also have shown a predilection for the development of papillary necrosis and generalized renal microvascular compromise. In these patients, compromised renal function is thought to be secondary to microvasculature damage from the chronic sickling of the erythrocytes. The renal damage from a UTI can compound the chronic renal insufficiency, leading to rapid worsening of the condition of these patients. They and all patients with underlying kidney disease or renal compromise should be approached conservatively, with hospitalization as deemed necessary for intravenous hydration and antibiotics.

Indwelling and Temporary Urinary Catheters

Treatment of asymptomatic bacteriuria in patients with indwelling catheters is not indicated. Antibiotic treatment results in the development of resistant microorganisms, whereas removal of the catheter leads to the spontaneous elimination of bacteria in many patients. Treatment of patients with a UTI in whom removal of the catheter is contraindicated includes urine culture and sensitivity, antibiotic therapy, replacement of the catheter, and strong consideration for hospitalization in those who exhibit altered vital signs, systemic symptoms, or a toxic appearance. These patients are at high risk for infection with an unusual pathogen and subsequent bacteremia. Urine culture with antibiotic sensitivity testing will help guide antibiotic therapy in this patient population.

The prevention of catheter-associated urinary tract infections (CAUTIs) has become an area of recent interest in the hospital setting since the Centers for Medicare and Medicaid Services (CMS) identified this condition as one of the six unacceptable diagnoses for payment if UTI was not present on admission.[21] CAUTIs are responsible for more than 80% of nosocomial UTIs and 40% of all nosocomial infections. Less than half of urinary catheters placed in hospitalized elderly patients have been found to be clinically indicated.[22] The most effective strategy for addressing CAUTIs is to prevent the infection from occurring by placing urinary catheters only when indicated and considering the use of intermittent catheterization and condom catheters when appropriate.

Differential Considerations

Bacterial UTI is the most common cause of dysuria with low-count infections. It is important, however, to consider the possibility of acute urethritis or acute vaginitis in these patients, as well as mechanical trauma or irritation (Tables 99-1 to 99-3; Fig. 99-1). Urethritis caused by *Chlamydia* may be seen in patients with acute dysuria; in fact, *C. trachomatis* may be present in up to 20% of women with dysuria. In general, if historical information includes contact with multiple sexual partners, a recent change in sexual partners, or a sexual partner with dysuria or discharge, *C. trachomatis* infection should be strongly considered. A pelvic examination should be performed, and culture specimens should be obtained to detect *C. trachomatis* and *N. gonorrhoeae*. Other causes of acute dysuria include infections with *Trichomonas vaginalis* and herpes simplex virus.

The dysuria of vaginitis most often is described as "external," the sensation being caused by the passage of urine over inflamed introital tissue. Elderly women may report dysuria secondary to atrophic vaginitis. In either case, a pelvic examination may be required. Urinary frequency and urgency are seldom if ever associated with a vaginal cause of dysuria.

Bacterial infection of the bladder is the most likely cause of dysuria in female patients. Most demonstrate positive results on urine cultures, with growth of more than 10^5 CFUs/mL of bacteria. This number is not absolute because 30 to 50% of patients have low-count bacterial infections as a cause of their symptoms. It has been suggested that low bacterial counts may represent an early phase of UTI.

Management

Simple Urinary Tract Infection

Options for treating uncomplicated lower UTI include single-dose therapy, short-course therapy (3-5 days), and the more traditional 7- to 10-day course of therapy (Table 99-4). *E. coli* remains the most common urinary tract pathogen and is susceptible to many antibiotic regimens. Emerging resistance to TMP-SMX has been noted in 15 to 32% of organisms.[23] In some areas of Europe, resistance to TMP-SMX is approaching 50%.[24] Risk factors for UTI from TMP-SMX–resistant *E. coli* include recent use of antibiotics (especially TMP-SMX), recent travel to areas with a high prevalence of resistance, and age younger than 3 years with daycare attendance.

Three days of therapy is more effective than single-dose therapy.[25] Three days of therapy have the advantages of improved compliance, lower cost, and reduced side effects. It currently is the recommended regimen for treatment of uncomplicated lower UTI. Despite emerging resistance, TMP-SMX remains the best first-line agent for 3-day regimens when compared with other commonly used antibacterials, owing to its low cost and effectiveness. Short-course 3-day therapy also is effective for asymptomatic bacteriuria in pregnancy. It is unclear whether this regimen can be used for symptomatic lower UTIs in pregnancy, so longer-course therapy is recommended. A regimen of 7- to 10-day therapy generally offers no benefit over shorter courses in uncomplicated

UTIs; however, it remains the standard of care in complicated infections (in patients with pregnancy, diabetes, or sickle cell anemia) for which cure rates are lower with shorter regimens.

The fluoroquinolones are considered first-line agents in regions in which the incidence of TMP-SMX resistance has approached 10 to 20%. Ciprofloxacin is the most commonly used drug and requires twice-daily dosing. Although more expensive than ciprofloxacin, gatifloxacin and levofloxacin offer once-daily administration, have the broadest activity, and have same-dose bioequivalence between oral and parenteral administration. Fluoroquinolones damage developing cartilage in animal studies and should be avoided in children.[26]

Nitrofurantoin and trimethoprim are excellent drugs for the treatment of acute bacterial cystitis. Nitrofurantoin is inexpensive and maintains low serum and high urine levels, with a bacterial resistance pattern that remains unchanged. Adverse reactions are primarily secondary to GI disturbance, but they may be alleviated by use of the macrocrystalline form (Macrodantin). Folate antagonists such as trimethoprim have a broader spectrum of activity than does nitrofurantoin. The addition of sulfamethoxazole further broadens the spectrum to include coverage for *Proteus* and *Klebsiella.* Folate antagonists carry a higher incidence of adverse

effects than nitrofurantoin, predominantly GI upset, yeast vaginitis, and rash. Addition of the sulfa component further increases the likelihood of side effects.

Except in pregnancy, ampicillin and amoxicillin should not be used empirically as first-line drugs for the treatment of uncomplicated UTI. Recurrence rates with use against ampicillin-resistant strains are high, and neither agent effectively eradicates the vaginal reservoir of pathogenic bacteria.

A useful adjunctive therapy for UTIs is phenazopyridine (Pyridium). It produces topical analgesia in the urinary tract and helps relieve dysuria. Patients should be cautioned that body secretions and excretions (e.g., tears, urine) will turn orange. This side effect can stain contact lenses and alarm unknowing patients.

Complex Urinary Tract Infection

Mild-to-moderate pyelonephritis can be safely treated on an outpatient basis with a fluoroquinolone for 10 to 14 days (first-line agent) or TMP-SMX (second-line agent) as long as the patient is able to eat and drink, has achieved adequate pain control, and has appropriate social support in the home. In many clinical centers, observation units have evolved to offer a short-stay (less than 24 hours) option for moderate cases in which immediate discharge for outpatient therapy may not be the optimal approach to management.[20]

Severe upper tract UTI necessitating hospitalization initially should be treated with parenteral antibiotics, with transition to oral therapy after the patient has been afebrile for 24 to 48 hours. Oral therapy should be continued for 2 weeks. Because 20% of cultures are resistant to ampicillin, cephalothin, and sulfonamides, antibiotic therapy should be initiated with a fluoroquinolone.

Hospitalization is required in the presence of clinical toxicity (fever, tachycardia, hypotension, vomiting), inability to take oral medications, an immunocompromised state, third-trimester pregnancy, inadequate social circumstances, failure of oral outpatient therapy, or urologic abnormalities or in patients with significant comorbid conditions, including heart failure or renal insufficiency. A subgroup of patients with upper tract UTI do not require immediate hospital admission but may benefit from intravenous hydration and pain and fever control, along with a first dose of an intravenous fluoroquinolone before discharge from the ED. If these patients do not have any contraindications as previously discussed and they improve clinically and are able to tolerate food and drink, they can be safely discharged home on a 10- to 14-day course of an oral fluoroquinolone with close primary physician follow-up. Urine culture with sensitivity testing and further diagnostic evaluation are not necessary in this patient population.

URINARY TRACT INFECTION IN CHILDREN

Perspective

UTI is a major bacterial disease of childhood; it is estimated that 0.8 to 1.5% of children have bacteriuria. The risk for development of UTI before 11 years of age is 3% in girls and 1% in boys.[6] The incidence of UTI in the neonatal period is higher in boys, but the infection becomes more prominent in girls during infancy and thereafter. In children aged 1 to 3 months, UTI is associated with a high incidence of sepsis (30%).[7] After the age of 3 months, the incidence of sepsis associated with UTI decreases (to 5%). Vesicoureteral reflux is a common risk factor for UTI and renal scarring in children.[12] Data suggest that the incidence of scar formation after acute pyelonephritis may be as high as 37%.

www.ketabpezeshki.com 66485457-66963820

Table 99-4 Treatment Regimens for Bacterial Urinary Tract Infections (UTIs)

CONDITION	CHARACTERISTIC PATHOGENS	MITIGATING CIRCUMSTANCE(S)	RECOMMENDED EMPIRICAL TREATMENT*
Acute uncomplicated cystitis in women	*Escherichia coli, Staphylococcus saprophyticus, Proteus mirabilis, Klebsiella pneumoniae*	None	Use 3-day regimens: oral TMP-SMX, trimethoprim, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin[†]
		Diabetes, symptoms for longer than 7 days, recent UTI, use of diaphragm, age >65 yr	Consider 7-day regimen: oral TMP-SMX, trimethoprim, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin[†]
		Pregnancy	Consider 7-day regimen: amoxicillin, macrocrystalline nitrofurantoin, cefpodoxime proxetil, or TMP-SMX[†]
Acute uncomplicated pyelonephritis in women	*E. coli*, *P. mirabilis*, *K. pneumoniae*, *S. saprophyticus*	Mild to moderate illness, no nausea or vomiting—outpatient therapy	Oral[‡] TMP-SMX, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin for 10-14 days
		Severe illness or possible urosepsis—hospitalization required	Parenteral[§] TMP-SMX, ceftriaxone, ciprofloxacin, ofloxacin, or gentamicin (with or without ampicillin) until fever gone; then oral[‡] TMP-SMX, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin for 14 days
		Pregnancy—hospitalization recommended	Parenteral[§] ceftriaxone, gentamicin (with or without ampicillin), aztreonam, or TMP-SMX until fever gone; then oral[‡] amoxicillin, a cephalosporin, or TMP-SMX for 14 days
Complicated UTI	*E. coli*, *Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Serratia* species, enterococci, staphylococci	Mild to moderate illness, no nausea or vomiting—outpatient therapy	Oral[‡] norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin for 10-14 days

Adapted from Stamm W, Hooton TM: Management of urinary tract infections in adults. N Engl J Med 329:1328, 1993.

TMP-SMX, trimethoprim-sulfamethoxazole.

*Treatments listed are those to be prescribed before the causative agent is known (Gram staining can be helpful); they can be modified once the agent has been identified. These recommendations are limited to drugs currently approved by the U.S. Food and Drug Administration, although not all of the regimens listed are approved for these indications. Fluoroquinolones should not be used in pregnancy. TMP-SMX, although not approved for use in pregnancy, has been widely used. Gentamicin should be used with caution in pregnancy because of its possible toxicity to eighth nerve development in the fetus.

[†]Multiday oral regimens for cystitis are as follows: TMP-SMX 160-800 mg every 12 hr; trimethoprim 100 mg every 12 hr; norfloxacin 400 mg every 12 hr; ciprofloxacin 250 mg every 12 hr; ofloxacin 200 mg every 12 hr; lomefloxacin 400 mg every day; enoxacin 400 mg every 12 hr; macrocrystalline nitrofurantoin 100 mg four times a day; amoxicillin 250 mg every 8 hr; and cefpodoxime proxetil 100 mg every 12 hr.

[‡]Oral regimens for pyelonephritis and complicated UTI are as follows: TMP-SMX 160-800 mg every 12 hr; norfloxacin 400 mg every 12 hr; ciprofloxacin 500 mg every 12 hr; ofloxacin 200-300 mg every 12 hr; lomefloxacin 400 mg every day; enoxacin 400 mg every 12 hr; amoxicillin 500 mg every 8 hr; and cefpodoxime proxetil 200 mg every 12 hr.

[§]Parenteral regimens are as follows: TMP-SMX 160-800 mg every 12 hr; ciprofloxacin 200-400 mg every 12 hr; ofloxacin 200-400 mg every 12 hr; gentamicin 1 mg/kg of body weight every 8 hr; ceftriaxone 1-2 g every day; ampicillin 1 g every 6 hr; imipenem-cilastatin 250-500 mg every 6-8 hr; ticarcillin-clavulanate 3.2 g every 8 hr; and aztreonam 1 g every 8-12 hr.

Principles of Disease

As in adults, *E. coli* is the predominant pathogen.[6] Age-related differences are recognized: In older boys *Proteus* often is isolated during UTI, whereas in newborn children, *Klebsiella* is more often the causative agent. The route of infection also is age related. It is thought that in the newborn period the bacteria are blood-borne (and often associated with generalized sepsis). In the older age group, as in adults, the ascending urethral route is primarily responsible for generating infection of the urinary tract.

Clinical Features

UTI often is overlooked in children because of inappropriate emphasis on classic signs and symptoms, with little regard to age variables. Nonspecific findings should be considered the rule and not the exception (Table 99-5). Pyelonephritis may be present without overt symptoms. A UTI in a febrile patient usually indicates pyelonephritis. An elevated blood urea nitrogen (BUN) level or hypertension in a child older than 2 months strongly suggests bilateral hydronephrosis or advanced renal parenchymal disease.

Neonates

Generalized septicemia often is the major manifestation of neonatal UTI.[12] Classically, feeding difficulties, irritability, and sluggishness are seen in this age group. Bacteremia is present in nearly 50% of cases.[6]

Table 99-5 Signs and Symptoms of Urinary Tract Infection by Age Group

NEWBORN	INFANT	PRESCHOOLER	SCHOOL-AGE CHILD
Poor feeding Vomiting Jaundice Hypothermia Fever Failure to thrive Sepsis	Poor feeding Vomiting Diarrhea Fever Strong-smelling urine	Abdominal pain Vomiting Strong-smelling urine Fever Enuresis Increased frequency of urination Dysuria Urgency	Fever Enuresis Increased frequency of urination Dysuria Urgency Costovertebral angle tenderness (flank pain)

Age 1 Month to 3 Years

The 1-month to 3-year age group has the most deceptive clinical presentation of UTI. Nonspecific findings are typical: fever, irritability, abdominal pain, vomiting, and failure to thrive. Occasionally, gross hematuria may be present.

www.ketabpezeshki.com 66485457-66963820

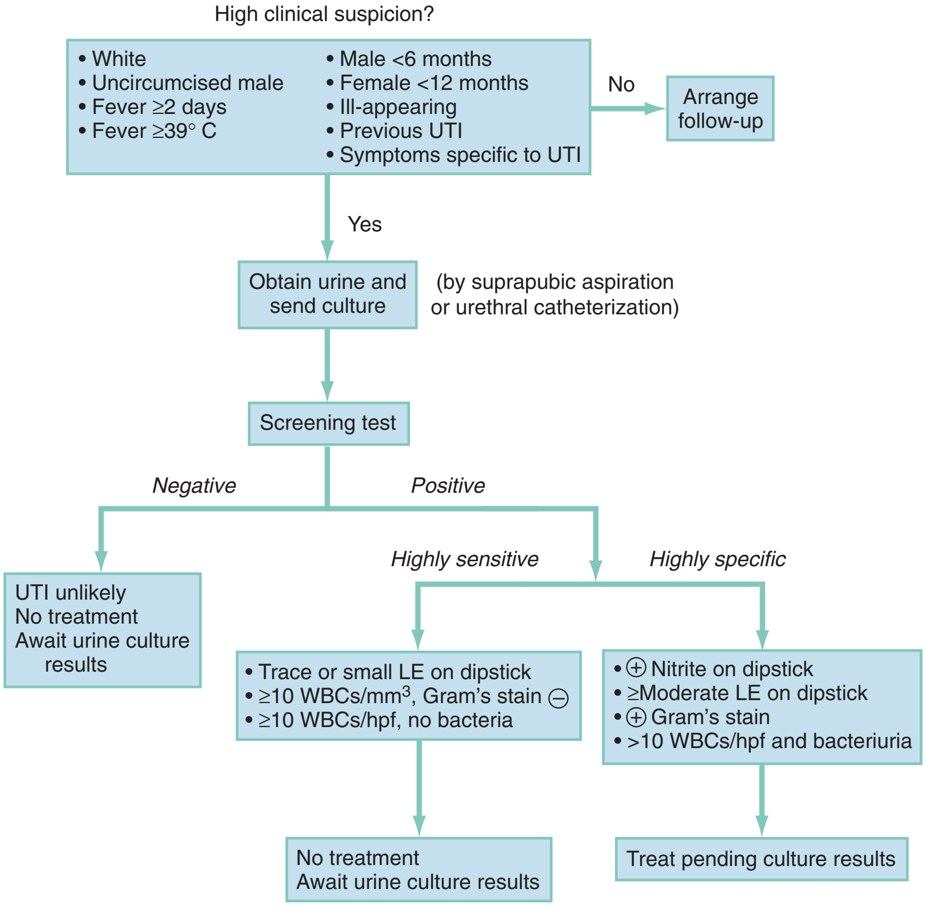

Figure 99-2. Screening for urinary tract infection (UTI) in febrile children (age 2 to 23 months) in the emergency department. *hpf,* high-power field; *LE,* leukocyte esterase; *WBCs,* white blood cells. (From Shaw KN, Gorelick MH: UTI in the pediatric patient. Pediatr Clin North Am 46:1111, 1999.)

Age 3 to 11 Years

In girls, abdominal pain, newly developed enuresis, and irritative voiding symptoms suggest the presence of UTI. In boys, fever is present in association with UTI in more than 50% of cases. Varying degrees of hematuria and irritative symptoms (urgency, dysuria) are present. *Proteus* is a common pathogen in this particular group. Most cases are simple, uncomplicated infections responsive to commonly used antimicrobial agents. The presence of certain signs and symptoms implies the possibility of serious underlying disease of the urinary tract. The most significant factors include a raised or palpable bladder, hypertension, abnormalities in electrolytes, acidosis, elevated BUN level, evidence of dribbling, poor urinary stream, and straining to void. If any of these factors is noted, prompt urologic referral or consultation is indicated. If the clinical picture is suggestive of an underlying obstructive process, emergency imaging is essential.

Diagnostic Strategies

Laboratory studies useful for diagnosing an infection of the urinary tract as previously described also apply to children. However, presumptive treatment may be indicated in high-risk patients based on clinical predictors and screening tests, as shown in Figure 99-2. Additional studies are dictated by the clinical setting and include renal function studies, a complete blood count, serum electrolyte panel, CT scan, voiding cystourethrography, and ultrasonography. Renal cortical scintigraphy is the most sensitive method of detecting pyelonephritis.

As described previously, urine collection often poses a challenge in a child with a suspected UTI. Catheterization or suprapubic bladder aspiration provides the most reliable specimen for determination of UTI.

Management and Disposition

As in adults, many therapeutic options are available for children with UTI. Sulfonamides, nitrofurantoin, TMP-SMX, cephalosporins, and aminopenicillins are effective.[6] Newborns and young infants should be treated with ampicillin and gentamicin on an inpatient basis. Sulfonamides and fluoroquinolones should be avoided in pediatric patients. Traditionally, inpatient treatment with parenteral antibiotics has been the standard of care for young children with suspected pyelonephritis. Oral therapy is acceptable in children with uncomplicated infections. These patients should be managed conservatively, and hospital admission is advised for children who are dehydrated, severely ill, or not tolerating oral fluids and for those with underlying structural abnormalities of the genitourinary system. In addition, family dynamics, which could affect compliance with medication, should be taken into consideration.

The appropriate duration of therapy currently is a subject of debate. Many experts believe that in children with uncomplicated lower UTI, short-course therapy can be used instead of the traditional 10-day regimen. Short-course (3-day) therapy is more widely accepted in adolescent girls. Once the decision to discharge a child has been made, the parents should be advised of signs of toxicity and the importance of compliance with medications.

www.ketabpezeshki.com 66485457-66963820

Parents should bring the child to the ED immediately if signs of toxicity develop and should arrange routine follow-up with the pediatrician if the child improves. The child should be seen for follow-up 2 to 3 days after the ED visit and again 2 to 3 weeks later (or 7 to 10 days after completion of the antibiotic course).

URINARY TRACT INFECTION IN MEN

Perspective

The incidence of UTI is much lower in men than in women. The route of infection in men is usually ascending, from the urethra to the prostate, to the bladder, and then to the kidney. Pathogenic organisms responsible for UTI in men are similar in type, regardless of the site of infection in the genitourinary tract. *E. coli* causes 80% of infections in men. UTI in men should be considered a complicated infection and requires a more extensive evaluation as well as a longer course of antibiotics.

Specific Disorders

Cystitis

Cystitis is rare in male patients in the absence of blunt trauma, prostate pathology, or instrumentation.[3] Chronic prostatitis, prostatic hyperplasia with obstruction, and previous instrumentation are the most common predisposing factors. Lack of circumcision and homosexuality are other recognized risk factors. Commonly, men with cystitis have symptoms of urinary urgency, frequency, dysuria, nocturia, suprapubic pain, and often low back pain. Gross hematuria occasionally occurs, but fever, chills, and flank pain generally are absent. On physical examination, suprapubic tenderness to palpation may be elicited. Pneumaturia may be present and is indicative of an infection with gas-forming bacteria. It also may indicate the presence of a vesicoenteric fistula, which often is caused by diverticulitis, although rectosigmoid carcinoma and regional enteritis are associated diseases as well. If fever and chills are present in association with irritative symptoms and difficulty voiding, acute bacterial prostatitis should be strongly considered. The most common pathogens found in men with cystitis are *E. coli, Proteus,* and *Providencia.*

A voided urine specimen should reveal pyuria, bacteriuria, and a variable degree of hematuria. Urine culture is indicated. If there are no signs of toxicity, the patient can be treated on an outpatient basis with any of the urinary antibacterial agents (TMP-SMX, nitrofurantoins, sulfonamides, or fluoroquinolones).

Three qualifying factors should be addressed in dealing with UTIs in men:

1. *Obstruction.* It is imperative that urinary obstruction be ruled out as a pathogenic mechanism. Infection and obstruction together can be catastrophic and lead to sepsis. Obstruction at the level of the prostate in older men is common and should be considered. Catheterization or bedside ultrasound examination may help to rule out retention. Suggestion of obstruction of the upper tracts based on lack of response to medical therapy necessitates performance of an abdominal noncontrast CT scan or ultrasound.
2. *Genitourinary tract anomalies.* UTIs in men may be secondary to underlying diseases of the genitourinary tract. Therefore all of these patients should be referred to a urologist for diagnostic studies.
3. *Catheterization.* Urethral catheterization should not be used to collect a urine specimen in men unless they are experiencing urinary retention. An inability to produce a specimen in the presence of infectious symptoms should be a major clue regarding the cause of the infection. If retention is suspected, catheterization for collection of residual urine is indicated. Referral for urologic consultation is recommended and hospital admission is prudent for a majority of these patients.

Pyelonephritis

Clinical features in men with acute pyelonephritis include flank and costovertebral angle pain, chills and fever, urinary frequency, urgency, and dysuria. Generalized malaise, nausea, and vomiting are early signs of systemic toxicity, suggesting impending gram-negative sepsis. These patients require hospitalization for intravenous hydration and antibiotic therapy, as well as pain and fever control.

A voided urine specimen usually reveals leukocytes, occasional leukocyte casts, a variable number of RBCs, and bacteria. Urine culture is essential in this patient population. Blood cultures should be performed if the clinical picture suggests sepsis. A complete blood count, renal function studies, and electrolyte studies are recommended. Uncomplicated pyelonephritis should not produce detectable alterations in the BUN level. In males, imaging with ultrasonography or an abdominal CT scan without contrast is required because the cause typically involves obstruction secondary to a stone, prostate pathology, stricture, or tumor. Catheterization for collection of residual urine may be indicated if urinary retention is suspected.

Prostatitis

Bacterial prostatitis is an infection of the prostate caused primarily by gram-negative organisms. More than 80% of cases are caused by strains of *E. coli;* the remainder are caused by *Klebsiella, Enterobacter, Proteus,* and *Pseudomonas* species. Patients with prostatitis may report dysuria and perineal and low back pain associated with fever, chills, and malaise. A rectal examination should be part of the workup in all men with symptoms suggestive of cystitis. Bacterial prostatitis is not a subtle disease, and patients will have an exquisitely tender and boggy prostate.

Acute bacterial prostatitis is an acute febrile illness characterized by chills, low back pain, and perineal pain. Irritative symptoms of voiding, including frequency, urgency, and dysuria, are present, along with various degrees of bladder outlet obstruction and retention. Patients often have constitutional symptoms of arthralgia, myalgia, and generalized malaise. Prostate examination reveals a tender, swollen gland that is firm and warm to touch. Palpation of an acutely inflamed prostate should be limited, to avoid the possibility of precipitating bacteremia or sepsis. Cystitis usually accompanies acute bacterial prostatitis; thus culture of voided bladder urine generally reveals the responsible pathogen.

Antimicrobial therapy has been shown to be beneficial and is recommended.[27] In patients without signs of systemic toxicity, a prolonged course of an antibiotic for 4 to 6 weeks is required. This may need to be repeated if only partial success is achieved. The following list represents an appropriate selection of drugs for *nontoxic* prostatitis:

1. Ciprofloxacin 500 mg orally (PO) twice daily; norfloxacin 400 mg PO twice daily; ofloxacin 400 mg PO twice daily or enoxacin 400 mg PO twice daily for 30 days
2. Trimethoprim with sulfamethoxazole (Bactrim), one double-strength tablet PO twice daily for 30 days

If the patient is toxic appearing with fever, chills, or urinary retention, hospitalization and parenteral antibiotics are warranted. The following antibiotic choices are appropriate for *toxic* prostatitis:

1. Ciprofloxacin 400 mg intravenously (IV) every 12 hours, or levofloxacin 500 mg IV every 24 hours

www.ketabpezeshki.com 66485457-66963820

2. Ceftriaxone 2 g IV every 24 hours with or without gentamicin 3 to 5 mg/kg/day

Some experts have recommended alpha-blocker therapy because the bladder neck and prostate are rich in these receptors and alpha-blockade may improve outflow obstruction and diminish prostatic reflux. Although this may facilitate the patient's recovery course, clinical trials are ongoing and this is not considered standard of care.[28]

If the patient is experiencing painful urinary retention, urethral catheterization should be avoided. Suprapubic needle aspiration or catheterization is much safer and more comfortable than urethral catheterization for initial management. A urologist should be consulted regarding management of all patients requiring suprapubic tube placement.

General support measures for outpatients should include bed rest, analgesics, antipyretics, hydration, and stool softeners.

Chronic Prostatitis

Patients with chronic prostatitis typically visit the ED when they experience an acute exacerbation of the disease. Clinical manifestations vary widely, but most patients report some degree of irritative voiding symptoms (frequency, urgency, dysuria), low back and perineal pain, and occasionally myalgias.[27] Fever and chills are uncommon except during an acute exacerbation of the chronic infection. A history of previous episodes of acute prostatitis may be absent. Findings on the physical examination, including examination of the prostate, often are unremarkable. The hallmark of chronic bacterial prostatitis is relapsing UTI caused by the same organism. Chronic bacterial prostatitis is the most common cause of recurrent UTI in men.

Antimicrobial therapy is recommended for the treatment of chronic prostatitis.[29] Most antimicrobials diffuse poorly from plasma into prostatic fluid. The fluoroquinolones achieve the highest concentrations in the prostate and are the drugs of choice, with cure rates of approximately 64%. The recommended dosages are as follows: ciprofloxacin 500 mg twice daily for 30 days; norfloxacin 400 mg twice daily for 30 days; enoxacin 400 mg twice daily for 30 days; or ofloxacin 300 mg twice daily for 6 weeks. TMP-SMX also is useful, with cure rates of 44 to 50%. The dosage is one double-strength tablet twice daily, but the optimal duration of therapy is unclear and may range from 4 to 16 weeks.

RENAL CALCULI

Perspective

Background

Urolithiasis constitutes a common clinical problem seen in the ED and affects 5 to 15% of the population worldwide, and recurrence rates are close to 50%.[30] From 1994 through 2000, presentations for urolithiasis nearly doubled, and all indicators point to a rise in the incidence of kidney stones in the general population.[31] Renal calculi are seen commonly in young adults and middle-aged men, with nearly 70% of all ureteral calculi occurring in individuals aged 20 to 50 years. Most ureteral calculi originate in the kidney and then pass into the collecting system.

Epidemiology

Various clinical syndromes involve metabolic alterations and are therefore associated with an increased likelihood of stone formation[32] (Box 99-2). Risk factors include age, male gender, and family history. In the United States, prevalence rates for renal calculi are 10% in men and 5% in women.[33]

Box 99-2 Risk Factors for Urolithiasis

Metabolic disease or disturbance
- Crohn's disease
- Milk-alkali syndrome
- Primary hyperparathyroidism
- Hypernitraturia
- Hyperuricosuria
- Sarcoidosis
- Recurrent UTI
- Renal tubular acidosis (type I)
- Gout
- Laxative abuse

Positive family history
Hot arid climates (southeast United States)
Male gender (white men affected more commonly than black men)
Previous kidney stone
Dehydration

UTI, urinary tract infection.

Principles of Disease

Overview

Multiple pathogenic factors interact to cause the formation of renal calculi. Renal calculi can be stratified into the following types: calcium, struvite, uric acid, and cystine.

Most stones (75%) are composed of calcium oxalate, alone or in combination with calcium phosphate. Hyperexcretion of calcium is a major contributor to stone formation and occurs in various clinical settings. The major dietary sources of calcium are cheese and milk, and hypercalciuria may occur in adults who ingest more than 1 quart of milk daily. Many conditions are associated with the development of hypercalciuria with increased risk of stone formation. The most common is hyperparathyroidism, in which calculi develop in 67% of patients. Peptic ulcer disease also may be a predisposing factor. These patients tend to ingest large amounts of calcium with food, in addition to absorbed alkali sources (sodium bicarbonate) and antacids. The other major component of calcium stones, oxalate, is influenced by diet. Hyperoxaluria occurs in the presence of small bowel disease, Crohn's disease, ulcerative colitis, and radiation enteritis.

Magnesium-ammonium-phosphate (struvite) stones account for approximately 15% of all renal calculi. Struvite stones occur almost exclusively in patients with UTI and often are referred to as "infection stones." They form as a result of urea-splitting organisms such as *Proteus, Providencia, Klebsiella, Pseudomonas,* and *Staphylococcus.* Distinctive features of these stones include common occurrence as staghorn calculi and the formation of "coffin-lid" crystals, often in the presence of alkaline urine.

Uric acid stones account for 10% of all stones in the United States. The basic causative factor is excessive excretion of uric acid in urine. Approximately 25% of patients with symptomatic gout have uric acid calculi, and the incidence of uric acid stones increases with the use of uricosuric agents. A distinctive feature of uric acid stones is their radiolucency. These stones infrequently take the form of staghorn calculi.

Cystine stones are rare and account for only 1% of stones. They are caused by an inborn error of metabolism that results in increased secretion of cystine and often occur as staghorn calculi.

Pathophysiology

Impaction along the genitourinary tract is a serious complication of renal calculi and can cause several physiologic changes. Once

www.ketabpezeshki.com 66485457-66963820

obstruction occurs, a rapid redistribution of renal blood flow results in a decrease in the glomerular filtration rate. As glomerular and tubular function decreases, renal excretion shifts to the unaffected kidney. Obstruction also causes a rapid decrease in ureteral peristaltic activity. In the presence of infection, both renal and ureteral function may be impaired. Complete obstruction of the ureters may lead to loss of renal function, with an increased incidence of irreversible damage after 1 to 2 weeks, including rupture of the renal calyx. Partial obstruction is associated with a lower likelihood of renal injury, but it may still result in irreversible damage.

Although calculus size and location are important determinants of the degree of disease, the major cause of progressive renal damage is associated infection. The stone behaves as a foreign body and leads to stasis and obstruction, decreasing host resistance and increasing the incidence of infection. Subsequent infectious complications include pyelonephritis, perinephric abscess, and gram-negative bacterial sepsis.

The three primary predictors of stone passage without the need for surgical intervention are calculus size, location, and the degree of patient pain at discharge. The most important factor that relates to passage of a calculus though the genitourinary tract is its size. Approximately 90% of stones smaller than 5 mm pass spontaneously within 4 weeks. This percentage decreases to 15% for stones 5 to 8 mm. Up to 95% of stones larger than 8 mm become impacted along the genitourinary tract, and lithotripsy or surgical removal may be required. Unless the stone is infected, renal damage is considerable, or there is obstruction of a solitary kidney, surgical intervention can be performed on an outpatient basis, provided the patient is able to tolerate oral intake and has adequate pain control. Spontaneous passage is more frequent with stones located below the midureter than with those located above the midureter. Patients with well-controlled pain on discharge are less likely to require surgical intervention than those who do not have well-controlled pain.

Renal calculi seldom cause complete obstruction. There are five sites along the ureter at which calculi are likely to become impacted (Fig. 99-3). First, a stone may lodge in the calyx of the kidney or pass into the renal pelvis and become lodged at the ureteropelvic junction. The relatively large renal pelvis (1 cm) narrows abruptly at its distal portion, where it is equal in diameter to its adjoining ureter (2-3 mm). The third region is near the pelvic brim where the ureter arches over the iliac vessels posteriorly into the true pelvis. The most constricted area along the ureter, and a common location for impaction, is at the ureterovesicular junction. This location is the site at which the ureter enters the muscular coat of the bladder (intramural ureter). At the time of diagnosis, up to 75% of stones are located in the distal third of the ureter. Finally, calculi may become lodged in the vesical orifice.

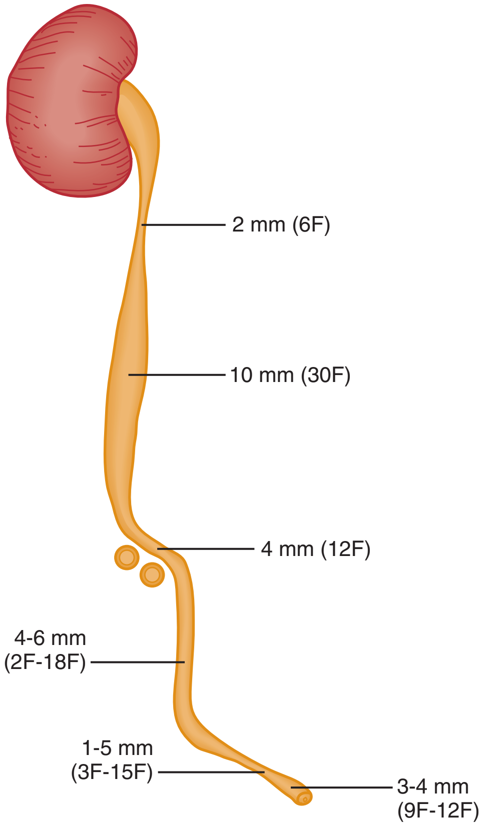

Figure 99-3. Variations in caliber of the ureter. *F,* French catheter size. (Adapted from Eisendrath, Rolnick. From Lich R Jr, et al: Childhood disorders and diseases. In Harrison JH, et al [eds]: Campbell's Urology, vol 1, 4th ed. Philadelphia, WB Saunders, 1978.)

Clinical Features

Signs and Symptoms

The onset of pain usually is abrupt, with a crescendo of extreme pain that begins in the flank, extends laterally around the abdomen, and radiates into the groin. Pain may radiate to the testicles in men and the labia majora in women. A constant, underlying dull ache in the flank is common between episodes of colic. The cause of colicky, severe flank pain is hyperperistalsis of the smooth muscle of the calyces, pelvis, and ureter, whereas the cause of a dull ache can be acute obstruction and renal capsular tension.

Autonomic nerve fibers that serve the kidney, testicle, and ovary are involved in the transmission of pain with renal calculi, and the location of the stone may be suggested by the pattern of pain. A stone located high in the ureter may cause pain that radiates to the testicle (or ovary). As the stone approaches the bladder, the pain may shift to the scrotum or vulva. Symptoms of urinary urgency and frequency often develop as the stone nears the bladder.

GI symptoms of nausea and vomiting are common in patients with renal colic. A third of patients experience gross hematuria, with or without blood clots in the urine. A history of fever and chills strongly suggests superimposed infection; such cases should be regarded as true urologic emergencies.

Physical Examination

A patient with renal colic often is in severe pain and paces or writhes in pain on the stretcher, unable to find a comfortable position. The skin usually is pale, cool, and clammy. Fever generally is not noted but if present strongly suggests infection. The abdominal examination may reveal signs of an early ileus with hypoactive bowel sounds. A decrease in peristalsis often accompanies renal colic, but abdominal tenderness usually is absent and flank tenderness is more common. It is essential that the abdomen be auscultated and palpated in search of bruits and thrills over the abdominal aorta and iliac vessels, because the clinical manifestations of aortic abdominal aneurysms may mimic those of renal colic. Patients commonly have intermittent pain that may nearly resolve between episodes of severe discomfort. The clinical picture may be misleading, with the patient's repeated attempts to secure relief from the pain misinterpreted as drug-seeking behavior, whereas actual pathology requiring medical attention is present.

www.ketabpezeshki.com 66485457-66963820

Diagnostic Strategies

Laboratory Tests

Urinalysis. The initial diagnostic step in the management of suspected renal colic is urinalysis. This simple, noninvasive test provides helpful information on various aspects of the patient's condition. In general, a dipstick test is performed first to evaluate for the presence of blood and infection. If results are abnormal, it is usually followed by microscopic analysis.

Sediment Analysis. RBCs generally are found in the urine of patients with urolithiasis. However, the absence of RBCs in urine does not exclude the diagnosis. From 10 to 20% of patients with documented urolithiasis have no microscopic hematuria.[34] Furthermore, there is no correlation between the degree of obstruction and the absence of hematuria. Although sterile pyuria can occur in the absence of infection as a result of ureteral inflammation, the presence of a UTI should be investigated if other clinical signs of infection are present, such as fever and chills. A urinalysis with culture should be performed to look for pyuria and bacteriuria and to measure nitrites and leukocyte esterase when infection is suspected.

Urinary pH. The kidney will not produce urine with a pH greater than 7.5 under normal conditions, so urinary pH greater than 7.5 should raise suspicion for the presence of urea-splitting organisms such as *Proteus*. Renal tubular acidosis and ingestion of absorbable alkali also may increase urine pH and should be considered in the differential diagnosis. A pH less than 5 often is associated with the formation of uric acid calculi.

Crystalluria. Historically, examination of urine crystals present on microscopic evaluation has provided a clue to the type of stone present. As a result of consolidation of urine testing to a central laboratory in most hospitals, this test is no longer routinely performed in most EDs.

Other Laboratory Tests. Serum uric acid levels are elevated in 50% of all uric acid stone formers, but this determination is not mandatory in the ED evaluation of the patient. Measurement of BUN and serum creatinine levels is not routine but should be done in patients who have a renal calculus with a solitary kidney, a transplanted kidney, or a history of renal insufficiency. A complete blood count may reveal a slightly elevated WBC count in patients with renal calculi that may be a result of demargination, but this is not a sensitive test and should be performed only in patients who are thought to be infected. A WBC count higher than 15,000/mm^3 or a significant left shift on the differential suggests active infection. Serum calcium and phosphorus levels can help screen for hyperparathyroidism, sarcoidosis, and other disorders of calcium metabolism, but this metabolic workup is not a necessary component of the ED evaluation of nephrolithiasis.

Imaging

Imaging is not needed in all patients with renal colic. If the signs and symptoms are atypical, the diagnosis is in question, the patient appears toxic, high-grade obstruction is suspected, or it is the patient's first episode of flank pain, imaging should be performed.

Computed Tomography. Non–contrast-enhanced helical (spiral) CT scanning is the standard imaging modality in the United States. It is sensitive and specific (98% and 100%, respectively, with a negative predictive value of 97%) in detecting both ureteral calculi and ureteral obstruction.[35] Other advantages include its ability to detect calculi as small as 1 mm in diameter and to provide direct visualization of complicating conditions such as hydroureter, hydronephrosis (Fig. 99-4), and ureteral edema. The CT scan is superior to other imaging modalities in its ability to recognize other pathology (malignancy, renal abscess, abdominal aortic aneurysm). It also has the advantage of lack of contrast exposure, short duration of testing, and ease of interpretation.

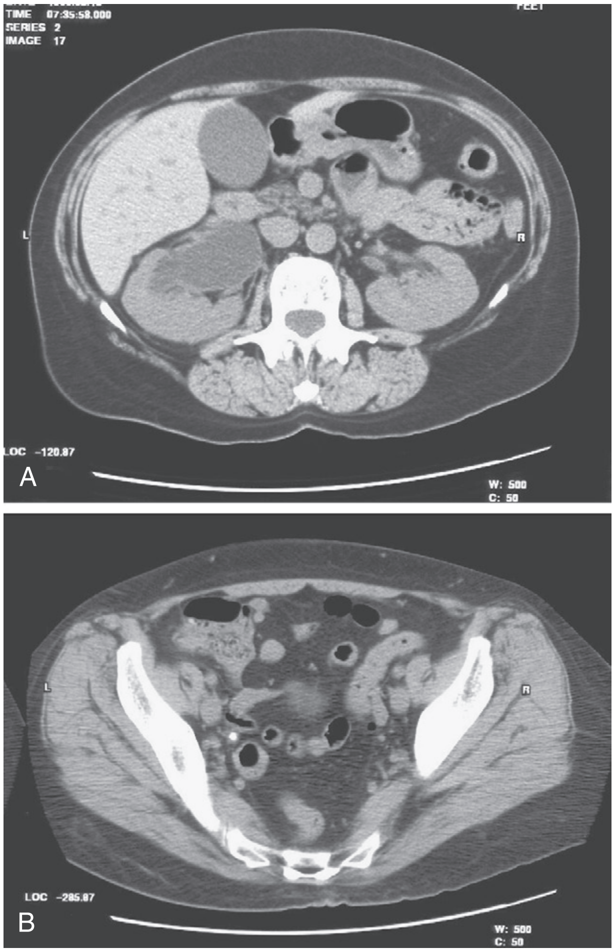

Figure 99-4. Computed tomography images obtained in a patient with renal colic. **A,** Right-sided hydronephrosis. **B,** Right ureteral calculi.

In patients who have signs and symptoms consistent with renal colic without a history of nephrolithiasis, noncontrast CT should be performed to improve diagnostic accuracy and guide management.[36] For unnecessary radiation to be limited and resource usage improved, patients who have a known history of nephrolithiasis and signs and symptoms consistent with renal colic in whom infection is not a concern do not need any form of imaging as long as they improve with medical management. Further imaging is appropriate in patients who have a history of nephrolithiasis who do not improve with treatment, who have a urinalysis showing infection, or in whom a more likely diagnosis than renal colic is suspected.[37]

Contraindications to CT scan imaging are few. Obese patients may be unable to undergo CT scanning if their girth or weight is beyond the capacity of the scanner. CT scanning should be avoided in pregnant patients because of radiation exposure to the fetus, and ultrasonography is the preferred diagnostic modality. CT scans may underestimate the actual size of the stone compared with the scout film from an IVP or kidney, ureter, and bladder (KUB) study. This limitation may adversely affect the management of patients with 5-mm stones, for example, in whom conservative therapy would be chosen on the basis of CT findings, although specific intervention would be more appropriate.[38]

Intravenous Pyelography. IVP is an accurate imaging modality to detect renal stones, but it is seldom used because CT scanning

www.ketabpezeshki.com 66485457-66963820

and ultrasonography have become first-line imaging modalities. It is very sensitive, capable of establishing the diagnosis of calculous disease in 96% of cases, and it can quantify the presence and severity of obstruction. Contraindications to the use of urographic contrast media include renal insufficiency with a serum creatinine greater than 1.5 mg/dL and previous reaction to radiocontrast material. The incidence of serious contrast reactions is extremely low, estimated to be 0.9 per 100,000. The value of IVP also is limited by the complexity and length of time needed to perform the procedure, which can take as long as 2 hours.

Ultrasonography. Ultrasonography is safe and easily performed, but it is much less reliable than CT scanning for detecting small (less than 5 mm in diameter) ureteral and midureteral stones.[39] Although only 37 to 64% sensitive for detecting calculi, ultrasound examination shows hydronephrosis with a sensitivity of 85 to 94% and a specificity of 100% (Fig. 99-5). It is the study of choice for ruling out hydronephrosis in a pregnant patient with pyelonephritis, if obstructive urolithiasis is a concern, or in obese patients who cannot undergo CT scanning.

Radiography of the Kidney, Ureter, and Bladder. A KUB film is the standard initial radiographic study done before injection of contrast medium during IVP. It is of limited usefulness on its own except as a progress film after CT has already identified a radiopaque stone. A KUB film is not reliable for diagnosing urolithiasis because it provides only presumptive evidence of calculi (less than 70% specificity), so it should be followed by a more definitive study or be avoided altogether. The most common radiographic densities seen on KUB films are phleboliths in the pelvic veins, which are spherical with a hollow (lucent) center, whereas calculi usually are irregularly shaped and solid. Calcified mesenteric lymph nodes also may add confusion, although unlike phleboliths, these densities commonly change position on subsequent films.

Most calculi (90%) are radiopaque, including calculi composed of calcium oxalate, cystine, calcium phosphate, or magnesium-ammonium-phosphate (Figs. 99-6 and 99-7). Uric acid stones, blood clots, and sloughed papillae are seen as "negative" shadows on radiographs. The most commonly overlooked calculi lie in the region over the sacrum, where small stones often are obscured by this bony density.

Differential Considerations

A number of significant clinical diseases can produce flank pain (Box 99-3) and should be considered in patients with symptoms suggestive of renal colic. Such conditions include abdominal aortic aneurysm, pyelonephritis, renal abscess, carcinoma, renal tuberculosis, papillary necrosis, and vascular compromise.

Acute pyelonephritis can cause severe renal pain. Urinalysis will aid in the differential diagnosis by demonstrating pyuria and bacteriuria. However, infection also can occur concomitantly with an obstructive stone. This combination constitutes a true urologic emergency and requires imaging (renal CT, ultrasonography, IVP) to rule out hydronephrosis, which may warrant immediate

urologic intervention for placement of ureteral stents or decompression of the renal pelvis by percutaneous nephrostomy.

Renal carcinoma also may produce flank pain, especially if hemorrhage has occurred within the tumor. An abdominal flat-plate radiograph (a KUB film) may demonstrate calcifications overlying the renal shadow, which often are seen in renal neoplasms. IVP may suggest the diagnosis, but CT scanning is the best imaging modality.

Papillary necrosis may cause renal colic as a result of passage of sloughed papillae down the ureter. It is most commonly seen in diabetics and in patients with a history of acute or chronic UTI. Sloughed papillae may be visualized on renal imaging and can be mistaken for an obstructive stone.

Renal pain, either colicky or noncolicky, may be caused by acute vascular compromise of a kidney. The pain of renal infarction is severe and occasionally associated with microscopic or gross hematuria. The acute vascular changes may be secondary to renal artery embolism, renal vein thrombosis, dissection of the renal artery, rupture of a renal artery aneurysm, aortic dissection, or abdominal aortic aneurysm. If a vascular cause is suspected, a contrast-enhanced CT scan or an angiogram should be performed. The most common of these relatively rare processes is renal artery embolism, which most often is of cardiac origin (as with atrial fibrillation, subacute bacterial endocarditis, or mural thrombus). An immediate traditional angiogram or CT angiogram scan is indicated because early diagnosis allows possible salvage of the ischemic kidney. Most renal artery aneurysms are small and seldom produce clinical manifestations. Dissection or rupture of a renal artery aneurysm is rare and causes shock and flank pain. Renal vein thrombosis often demonstrates microscopic hematuria and proteinuria. The KUB film may show an increased renal shadow, and in the early stages, contrast studies show decreased function of the affected kidney. Predisposing factors for renal vein thrombosis include nephrotic syndrome, malignancies, and pregnancy.

A renal or perinephric abscess may cause flank pain, fever, and a palpable mass. Ultrasonography or a CT scan should be performed. A chest radiograph may demonstrate a pleural effusion or elevation of the diaphragm. Both renal and perinephric abscesses require hospitalization for drainage, intravenous fluids, antibiotics, and determination of the underlying cause.

Management

General Approach

Patients with renal stones generally are in severe pain and are unable to find a comfortable position. Often the history and physical examination, combined with the finding of hematuria, allow a presumptive diagnosis to be made and therapy to be initiated. The first priority is adequate pain control. Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line agents, but parenteral administration often is necessary because of nausea and vomiting. Intravenous ketorolac or diclofenac provides rapid effective analgesia with minimal side effects. In addition to their analgesic effects, NSAIDs decrease the pain of renal colic by decreasing ureterospasm and also reduce renal capsular pressure by diminishing the glomerular filtration rate in the obstructed kidney. Accordingly, caution is advised with use of these agents in patients with underlying renal insufficiency or peptic ulcer disease. An antiemetic may be useful if the patient has nausea, and intravenous fluids should be given to the vomiting patient who is unable to tolerate liquids and who is likely to undergo an imaging procedure. There are no definitive studies proving that high-volume fluid therapy in acute renal colic facilitates stone passage or improves outcomes.[40]

Narcotics (morphine sulfate or hydromorphone) also are very effective in providing rapid analgesia, faster than NSAIDs. However, they carry a higher incidence of side effects than that noted with NSAIDs. The combination of NSAIDS and opiates is an acceptable approach that may reduce length of stay in the ED.[41] Little evidence in the literature supports the use of anticholinergics or steroids for the treatment of acute colic.

Outpatient Management

Most patients with nephrolithiasis may be safely discharged from the ED. Current guidelines recommend urologic intervention in patients with symptoms persisting for longer than 2 months.[32] The patient should be instructed to drink a moderate amount of fluids, to take analgesics as needed for pain, and to engage in activity as tolerated.

Medical expulsive therapy (MET) is another potentially useful treatment modality in the management of distal ureteral stones, although initial reports of its efficacy have recently been questioned.[43] Because ureteral smooth muscle contraction is mediated by intracellular calcium and by the autonomic nervous system, it is thought that alpha$_1$-antagonists and calcium channel blockers facilitate distal stone expulsion and decrease the time to spontaneous stone passage.[44] These agents are presumed to work by blocking ureteral smooth muscle contraction and improving antegrade

www.ketabpezeshki.com 66485457-66963820

stone movement. No published studies have addressed the usefulness of medical expulsion therapy with stones larger than 6 mm in the absence of shockwave lithotripsy, and a recent study with over 3000 patients showed that alpha-adrenergic antagonists are more effective than calcium channel blockers, although both forms of MET are acceptable.[45] Although still not considered essential in the treatment of nephrolithiasis, MET therapy seems to be effective in some patients and is safe.

Proper discharge instructions should include work and driving restrictions for patients taking narcotics. In addition, patients with first-time stones or those who have not had chemical analysis of their stones can strain all urine with a strainer manufactured for this purpose. If such a device is not available, patients may simply void into a glass jar; the calculus should be visible at the bottom. The stone can be submitted to the follow-up urologist for analysis. Patients should be instructed to return to the ED immediately for intractable or severe pain, persistent nausea and vomiting, fever or chills, or difficulty voiding. Finally, outpatient urologic evaluation is standard for ED patients with acute ureterolithiasis.

Indications for Hospital Admission

Hospital admission should be sought for patients who are severely dehydrated, are experiencing unrelenting pain or vomiting, or have an underlying urinary infection (Box 99-4). Sepsis and renal damage are risks in the presence of obstruction and infection, so admission to the hospital for symptomatic therapy is inadequate. These patients require urologic consultation to evaluate the need for drainage and for relief of the obstruction. If signs of sepsis (tachycardia, fever, hypotension, shock) are present, antibiotics and fluid resuscitation should be administered pending urologic evaluation. Immediate operative intervention may be indicated to provide drainage and relieve the obstruction.

A patient returning to the ED with persistent colic does not need a second imaging study if the stone was identified previously. In such cases a KUB film may localize the stone. An intervention by the urologist may be necessary if the stone has not progressed along the genitourinary tract. Several interventional strategies are available to the urologist for the management of stones that do not pass spontaneously. Optimal therapy depends on the size, location, and composition of the stone. Extracorporeal shock wave lithotripsy (ECSWL) has proved to be effective for stones located in the kidney, with a greater than 85% clearance rate. Upper ureteral stones also may be cleared with a high success rate when ECSWL is performed after ureteroscopic manipulation of the stone to a more proximal position. Percutaneous nephrolithotomy, which establishes a tract from the skin to the collecting system, is used for stones too large or hard for ECSWL by removing them directly from the renal pelvis.

Box 99-4 Indications for Hospital Admission of Patients with Urologic Symptoms

Absolute
- Obstructing stone with signs of urinary infection
- Intractable nausea or vomiting
- Severe pain requiring parenteral analgesics
- Urinary extravasation
- Hypercalcemic crisis

Relative
- Significant comorbid illness complicating outpatient management
- High-grade obstruction
- Leukocytosis
- Solitary kidney or intrinsic renal disease
- Psychosocial factors adversely affecting home management

BLADDER (VESICAL) CALCULUS

Although calculi generally form in the kidneys, they also may originate in the bladder. Bladder stones are different from renal stones. In the United States, bladder stones occur almost exclusively in elderly men, often as a complication of other urologic disease. The most common cause is infection of residual bladder urine with urea-splitting organisms. The other common cause of vesical stones is an indwelling catheter. Disorders predisposing to the formation of bladder stones include bladder neck obstruction (usually secondary to prostatic hyperplasia), neurogenic bladder, vesical diverticula, damage from irradiation, and schistosomiasis.

The presenting manifestations most often are pain on voiding and hematuria. The patient may report a sudden interruption of the urinary stream, which strongly suggests a vesical stone that intermittently obstructs the bladder outlet. Frequency, urgency, and dysuria are described by up to 50% of patients, and UTI is common. Physical examination is rarely rewarding because signs may be minimal. Rectal examination may reveal an enlarged prostate or a prostatic malignancy. Poor sphincter tone may suggest a neurogenic bladder. Urinalysis generally reveals pyuria, bacteriuria, and hematuria. Plain radiographs of the pelvis reveal a bladder stone in 50% of cases. Contrast scans may demonstrate obstructive changes in the upper tracts or bladder diverticula. Ultrasonography also is useful in the diagnosis of bladder stones.

ACUTE SCROTAL PAIN

Perspective

Several unique disorders encountered in the ED setting produce scrotal pain. It is crucial to determine the exact causative disorder in such cases because testicular torsion, a common cause of scrotal pain, represents a surgical emergency requiring rapid recognition and treatment. Other causes of scrotal pain require less invasive and time-dependent therapies, such as antibiotics for epididymitis and observation for benign masses or torsion of the appendix of the testes.

Principles of Disease

Anatomy

Knowledge of testicular landmarks is essential for examination of the patient with an acute scrotal mass. Figure 99-8 demonstrates the normal anatomy of the scrotum and testis. A normal scrotum is relatively symmetrical, and both testicles are of equal mass and volume. The left testicle often is higher than the right, because its blood flow empties into the large, low-pressure vena cava, whereas the right drains into the relatively smaller, high-pressure renal vein. A normal testis is found in the vertical axis with a slight forward tilt, and the epididymis is above the superior pole in the posterolateral position.

Physical Examination

On examination of the testis, any tenderness to palpation, discrepancies in size, loss of testicular landmarks, or discoloration should be noted. The epididymis is located posterolateral to the testis and is normally nontender and soft. The cremasteric reflex is elicited by stroking or pinching the inner aspect of the thigh; more than 0.5 cm of elevation of the ipsilateral testicle is considered evidence of a normal reflex. This reflex normally is absent in 50% of male infants younger than 30 months of age.

www.ketabpezeshki.com 66485457-66963820

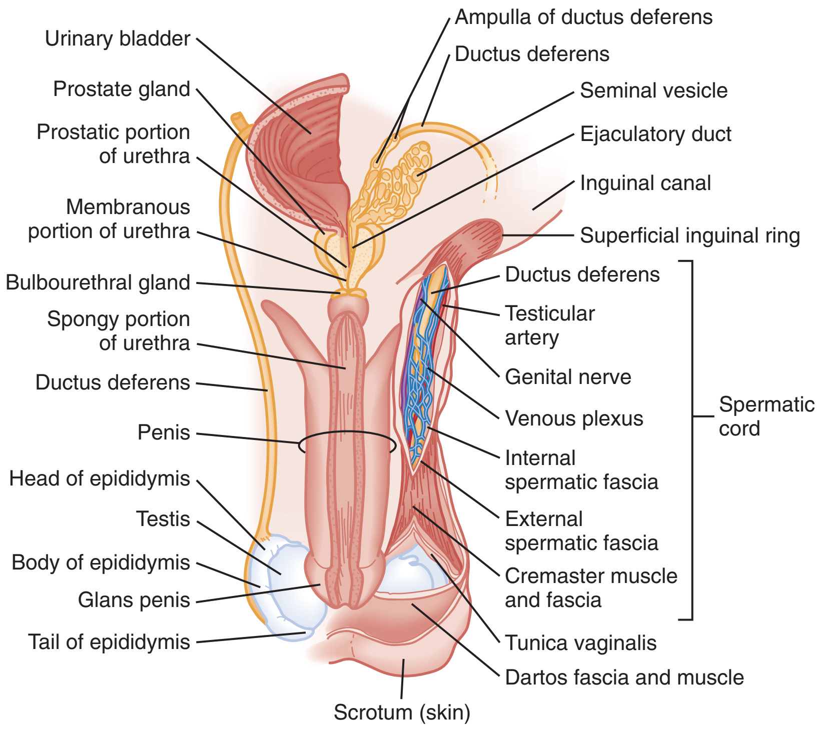

Figure 99-8. Testes, epididymis, ductus deferens, and glands of the male reproductive system. (From Seeley RR, et al [eds]: Anatomy and Physiology. New York, McGraw-Hill, 1989.)

Differential Considerations

Acute scrotal pain can arise with testicular torsion, epididymitis, torsion of the appendix of the testis, testicular tumor, or a hernia. Testicular torsion is the most important causative disorder to be excluded because any delay in treatment of this condition beyond 6 hours is associated with increased risk of testicular loss and infertility (Box 99-5).

Specific Disorders

Testicular Torsion

Perspective. Most studies suggest that testicular torsion is present in approximately 16 to 42% of patients coming to the ED with scrotal pain.[46] However, this is likely an overestimation resulting from selection bias, as most studies include only patients for whom suspicion of torsion is high, such as those evaluated by a urologist. A more recent retrospective study identified torsion in only 3.2% of all children brought to the ED with scrotal pain.[47] Nevertheless, torsion remains the most common cause of the acute scrotum in prepubertal boys, with a peak incidence in the first year of life. It also has a second peak incidence at puberty, when the rapid increase in testicular volume predisposes the testis to torsion. It can occur in adulthood, as evidenced by a retrospective review of data for 44 patients with torsion, of which 17 were older than 21 years of age.[48] Factors that increase the likelihood of torsion include horizontal lie of the testis, increased length of the spermatic cord in the scrotum, and a history of cryptorchidism. It is interesting to note that low ambient temperature has also been associated with testicular torsion, presumably because it induces contraction of the cremasteric muscles.[49]

Principles of Disease. With torsion, an extravaginal or intravaginal defect of the testis leads to twisting of the spermatic cord and decreased blood supply to the testicle. The cremasteric muscle surrounds the spermatic cord, and in the normal testicle, the testicle does not rotate when the cremasteric muscle contracts. In patients with torsion, however, the anatomic defect allows the tunica vaginalis to insert higher on the testicle, where it encircles the epididymis and distal spermatic cord. When the cremasteric muscle contracts in this abnormal scrotum, there is more room for the testicle to move, and it twists around the spermatic cord. Its movement resembles the ringing of the clapper in a bell—hence the description of a “bell clapper” deformity. By contrast, extravaginal defects occur almost exclusively in neonates and arise because the testicle lies outside of the tunica vaginalis, where it is prone to rotation. Torsion in neonates often is congenital, and by the time the condition is noted at birth, the testicle is not salvageable.

Testicular trauma also has been associated with torsion and has been noted in the literature to occur after motor vehicle collisions, straddle injuries, and athletic injuries. In these instances, the symptoms of torsion often are misattributed to the trauma itself, delaying the diagnosis. As a result, testicular salvage rates are only

www.ketabpezeshki.com 66485457-66963820

40% after groin trauma. To prevent loss of the testicle, scrotal pain persisting for an hour after any traumatic injury should raise suspicion for concomitant torsion of the testis.

As the testicle twists around the spermatic cord in torsion, it initially hinders venous return. Persistent torsion produces arterial obstruction, leading to ischemia and eventual necrosis of the testicle. With increasing degrees of rotation of the cord, ischemia increases, and infarction of the testicle occurs much more rapidly. Unfortunately, no clinical method has been devised for determining the extent of rotation of the testicle and the resultant likelihood of rapid ischemia. The duration of vascular obstruction also affects the ability to salvage the testicle; torsion recognized within 6 hours is associated with testicular salvage rates of 80 to 100%, whereas persistence of symptoms for 24 hours or longer is associated with nearly universal loss of the testicle.[50]

Clinical Features. Patients typically report sudden onset of scrotal pain that awakens them from sleep or develops several hours after physical activity. The pain arises in the scrotum, lower abdomen, or inguinal area. Patients with torsion tend to seek medical attention earlier than those with other causes of acute scrotal pain. However, the mean time of presentation is still 9.5 hours into the disease course, which makes expedient diagnosis and treatment very important for this time-sensitive condition. Up to 29% of patients with testicular torsion describe similar pain in the past, caused by previous intermittent torsion in a predisposed testicle. Patients often report nausea and vomiting or abdominal pain caused by reflex stimulation of the celiac ganglion.[47] Although a history of scrotal trauma reduces a patient's likelihood of having testicular torsion, approximately 10% of patients with testicular torsion report prior acute blunt trauma to the scrotum. There are no historical factors, including nausea, vomiting, abdominal pain, fever, urinary symptoms, or a history of trauma, that accurately or reliably differentiate torsion from other causative disorders (Table 99-6). Similarly, age cannot reliably be used to discriminate between torsion and other causes of acute scrotal pain.[49]

The physical examination is much more reliable than the history in determining the presence of testicular torsion. The most common finding is loss of the cremasteric reflex, observed in nearly 100% of patients older than 30 months with torsion. In a retrospective review of 245 patients with acute scrotal swelling, none of the patients with a cremasteric reflex had torsion.[51] However, a more recent ED-based study identified a normal cremasteric reflex in 19 of 62 patients with testicular torsion.[52] Therefore clinicians cannot rely on the presence of an intact cremasteric reflex to rule out torsion. Moreover, in asymptomatic children younger than 30 months, this reflex is often absent. Patients with torsion frequently have a tender, firm testicle that can be higher than the contralateral testicle (the odds ratio in one study was 58.8 for this finding) owing to shortening of the spermatic cord as it twists.[47] This difference in testicular heights can be difficult to ascertain because many individuals have differential testicular heights at baseline. Twisting also can leave the testicle in the transverse position and displace the epididymis from its usual location along the posterior aspect of the scrotum. Often the patient's scrotum is so swollen and tender that a complete physical examination is impossible. After 24 hours the physical examination is not particularly helpful because many of the aforementioned findings are no longer present. Despite the limitations of the physical examination, any patient with acute onset of scrotal pain and any of the aforementioned physical findings should be considered to have torsion until proven otherwise.

Diagnostic Strategies. In patients in whom the history and physical findings strongly suggest torsion, emergent surgical consultation is warranted. If the diagnosis is equivocal, adjunctive tests should be performed to determine the cause of the pain. Although clinical decision rules may eventually exist to guide imaging decisions, current rules have been based on small populations of children at single EDs and have not been validated.[53] Although urinalysis results suggestive of infection are consistent with epididymitis, such findings also may be noted in patients with torsion and concomitant UTI. Similarly, a complete blood count does not adequately differentiate torsion from alternate causes of the acute scrotum.

Ultrasound imaging for testicular torsion has a sensitivity of 88 to 100% and specificity approaching 90%.[54] With a 7- to 10-mHz high-frequency probe used on the supine patient, the asymptomatic testicle should be examined first, and the optimal settings for visualization and measurement of blood flow should be determined. In contrast to this testicle, the torsed testicle typically will be hypoechoic and enlarged (Fig. 99-9). False-negative findings occur when the testicle is examined early in the course of the disease, when blood flow is still present, and with intermittent torsion. Examination of the spermatic cord for twisting, instead of the testicle itself, has been shown to reduce the frequency of these false negatives. Color Doppler techniques can improve the specificity of ultrasound imaging to 100% by demonstrating reduced blood flow to the affected testicle. Doppler studies can be more difficult to interpret in younger boys because blood flow is physiologically low in the testicles of prepubertal boys. As many

Table 99-6 Differentiation among Causes of the Acute Scrotum

FEATURE	TESTICULAR TORSION	APPENDIX TORSION	EPIDIDYMITIS
Age	<1 yr, puberty	7-14 yr	Adult
Onset	Hours	1-2 days	Days to weeks
Location of pain	Entire testicle	Upper pole	Epididymis
Systemic symptoms	Nausea	None	Fever
Cremasteric reflex	No	Intact	Intact
Pyuria	Rare	No	Yes
Ultrasound findings	Diffusely hypoechoic Asymmetrical testicles Normal or decreased flow Spermatic cord knot	Focally hypoechoic Symmetrical testicles Normal flow	Hypoechoic epididymis Symmetrical testicles Increased flow
Treatment	Surgery	Supportive	Antibiotics; prepuberty: supportive only

Note: No single finding in patients with an acute scrotum can reliably differentiate torsion from other causative disorders. When torsion is a diagnostic possibility, prompt urology consultation is mandatory.

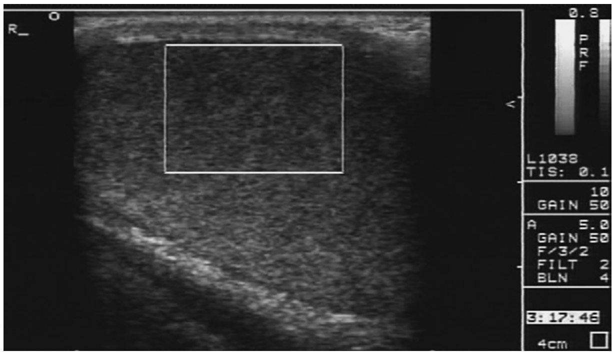

Figure 99-9. Doppler ultrasound image showing a testicle with no flow as a result of torsion. (From Blaivas M, Brannam L: Testicular ultrasound. In Rosen C, Wolfe R [eds]: Ultrasound in Emergency Medicine. Emerg Med Clin North Am 22:730, 2004 [Figure 7].)

as 50% of boys younger than 8 years do not show intratesticular flow.[55] This hypovascularity can result in false-positive diagnoses, which could potentially lead to unnecessary surgical exploration. Comparison with the contralateral testicle can help avoid this misdiagnosis, as in normal patients, blood flow to the two testicles will be similar.

The color Doppler appearance of the testicle depends on the degree of twisting of the spermatic cord. With 180 degrees or less of twisting of the cord, venous flow from the testicle ceases but arterial flow persists. This leads to edema of the testicle on ultrasound that can be misinterpreted as inconsistent with torsion. Although technically more difficult to perform, direct visualization of the spermatic cord for torsion can prevent this misdiagnosis. With torsion, this should reveal a knot in the spermatic cord above the testis, often referred to as a "snail shell" or "whirlpool." A study of 919 children found this sign had a sensitivity and specificity close to 100%. In contrast, with more than 180 degrees of twisting of the cord, arterial flow also ceases, leading to a lack of Doppler signal on ultrasound.[55]

Parenchymal echo texture on ultrasound may help predict the viability of the testicle. Homogenous echo texture of the parenchyma has been associated with higher likelihood of testicular salvage. A retrospective review of 25 cases of testicular torsion found a zero recovery rate in testes with heterogeneous echogenicity.[56] In the future, parenchymal appearance may help determine patients who are appropriate candidates for emergent surgery.

Color Doppler ultrasound imaging has the advantage of being an inexpensive, rapid test, readily performed in the ED setting. It is helpful when it demonstrates torsion in cases with equivocal findings on the history and physical examination, but it does not have sufficient sensitivity to rule out a diagnosis of torsion. A recent analyses of 669 scrotal ultrasounds revealed a 98% negative predictive value for torsion.[57] A urologist should evaluate any patient in whom ultrasound findings are negative but history and physical findings are suggestive of torsion. Moreover, ultrasound examination should never delay evaluation by a urologist in any patient with probable torsion.

Radioisotope scanning has the advantage of improved sensitivity compared with ultrasonography, but it is a time-consuming test inappropriate for use in the ED.

Management. The first step in management of very strongly suspected testicular torsion is immediate consultation with a urologist. The longer the spermatic cord remains twisted, the lower the likelihood of testicular salvage. More than 90% of affected testicles can be saved within 6 hours of symptom onset, but by 24 hours, 100% are lost.[50] In addition, early consultation allows the urologist to accompany the patient to ultrasound—if imaging is obtained—where images can be reviewed in real-time with the radiologist. After consultation, intravenous access is established and analgesia is provided either systemically or with a block of the spermatic cord.

If the urologist is not readily available, then manual detorsion should be attempted as follows. The operator stands at the supine patient's feet and rotates the affected testicle away from the midline, as if turning the pages of a book. If this maneuver is successful, patients should report immediate improvement of symptoms. Most studies suggest that this technique untwists about one fourth of testicles under torsion; other studies, however, have achieved success rates as high as 80%. Some torsions involve rotation through 720 degrees, so continuing the untwisting maneuver past 360 degrees is recommended if no improvement is obtained initially, especially in cases in which torsion is strongly suspected. Analgesics should be administered before this procedure. Regardless of the outcome with manual detorsion, patients still require surgical evaluation. Often urologists will perform bilateral orchiopexy after successful manual detorsion, to prevent recurrence. In addition, evaluation by a urologist should never be delayed to perform this or any other test or maneuver.

Once the diagnosis of testicular torsion has been established, the clinician should determine if emergent removal of the torsed testicle is necessary. Many studies suggest that emergent surgical exploration is unnecessary when symptoms of testicular torsion persist beyond 24 hours because the testicle is not salvageable. Other studies suggest that persistence of symptoms beyond only 10 hours, combined with absence of flow on ultrasound, predicts irreversible testicular necrosis.[58] Unfortunately, in the ED it is difficult to know if torsion is complete, and with incomplete torsion, surgery can achieve salvage beyond 24 hours. In addition, surgical removal of the necrotic testicle reduces pain and the duration of other symptoms.[52] Therefore, emergency clinicians should not rely on the duration of symptoms to determine management; all patients require emergent urologic evaluation.

Disposition. Rapid diagnosis of testicular torsion is essential and should be followed by emergent surgical scrotal exploration and bilateral orchiopexy, if necessary. Loss of the testicle most commonly is a result of delay in seeking medical attention. However, almost 30% of cases of failed testicular salvage have been attributed to misdiagnosis, and another 13% to a delay in treatment after the proper diagnosis was established. Misdiagnosis nearly universally leads to orchiectomy and represents a common source of litigation.[59]

Torsion of Appendages of the Testis

Perspective. A normal scrotum has several vestigial appendages that also can twist and become ischemic, with resultant scrotal pain. This process is most common between 7 and 14 years of age, with a mean age of 10 years. In retrospective analyses, torsion of an appendage rivals testicular torsion as the most common cause of the acute scrotum.

Principles of Disease. The appendix testis, a remnant of the paramesonephric duct, is present in 92% of patients. It is located on the superior aspect of the testicle between the testis and the epididymis. The appendix epididymis, a remnant of the mesonephric duct, is the second most common testicular appendage, found in approximately 23% of patients. It typically is located on the tip of the epididymis (Fig. 99-10). These appendages are prone to torsion owing to their pedunculated shape. After several days of ischemia from torsion, they will undergo necrosis with eventual reabsorption. Their loss does not permanently affect fertility or have any impact on surrounding structures.

Clinical Features. As with testicular torsion, patients with torsion of an appendage complain of scrotal pain but report milder symptoms with a more gradual onset. These patients usually seek

www.ketabpezeshki.com 66485457-66963820

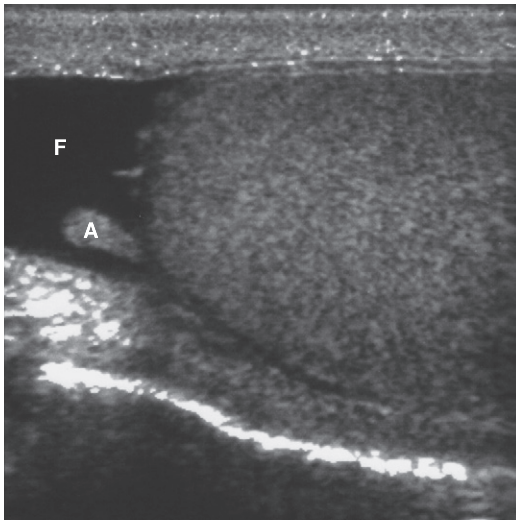

Figure 99-10. Ultrasound image showing the testicular appendage *(A)* surrounded by a hydrocele *(F)*. (From Blaivas M, Brannam L: Testicular ultrasound. In Rosen C, Wolfe R [eds]: Ultrasound in Emergency Medicine. Emerg Med Clin North Am 22:729, 2004 [Figure 6].)

medical attention in the ED later than patients with testicular torsion, commonly after 48 hours of symptoms. Also in contrast to testicular torsion, the pain often can be localized to one point on the testicle. These patients report nausea, vomiting, urinary symptoms, or previous episodes of similar pain less commonly than patients with testicular torsion.[52]

On physical examination, twisting of the appendix testis leads to formation of a hard, tender, 2- to 3-mm nodule at the upper pole of the testicle. Unlike in testicular torsion, the entire testicle is not tender. The testicle also does not change in overall size, and the scrotum typically does not swell until late in the disease process. The cremasteric reflex typically is intact. On transillumination, the ischemic appendage may appear as a blue dot. Although highly specific for torsion of the appendix, this sign is found in as few as 10% of patients. A reactive hydrocele can form during the course of disease, obscuring the physical findings.

Diagnostic Strategies. Urinalysis does not show evidence of infection. On ultrasound imaging, the appendix under torsion will appear hypoechoic. When the appendix then enlarges, the "Mickey Mouse" sign may be apparent on the transverse view, as a result of juxtaposition of the testicle, enlarged appendix, and epididymis. Color Doppler ultrasound can show decreased flow in both normal and torsed appendages. With torsion of the appendix, a hypoechoic spherical nodule with a diameter greater than 5 mm is present over the superior aspect of the testicle.[55]

Differential Considerations. Other diagnostic entities such as testicular torsion, epididymitis, and testicular tumor should be considered and excluded before a firm diagnosis of torsion of an appendage can be made.

Management and Disposition. If testicular torsion is ruled out, surgical excision of the appendix is rarely necessary. Treatment consists of scrotal support, ice, and NSAIDs. Resolution of symptoms can be expected within 7 to 10 days. Surgical excision is reserved for uncontrollable pain.

Epididymitis

Perspective. Epididymitis is the most common intrascrotal inflammatory disease. Nearly one half of the cases arise in young men aged 20 to 29 years, but the disease also has affected patients from 4 months to 76 years of age.[60] If untreated, it can lead to orchitis, testicular abscess, and rarely sepsis.

Principles of Disease. The epididymis is a tightly coiled tubular area along the posterior aspect of the testes, where sperm mature before their transit to the vas deferens. It becomes infected when organisms travel retrograde from the vas deferens. With infection, the testis may become edematous secondary to passive congestion and inflammation. Resolution of epididymitis typically concludes without sequelae, but rarely, men will develop infertility that persists after bacteriologic cure.

Pathophysiology. The particular organisms involved in the infection depend on the sexual activity of the patient. Although the literature classically describes men younger than 35 years of age as prone to *C. trachomatis* and *N. gonorrhoeae* infections, all sexually active men, regardless of age, are at risk for epididymitis from these organisms. *C. trachomatis* is much more common, being identified in 47% of patients younger than 35 years, with *N. gonorrhoeae* seen in 20%.[61] *Ureaplasma* also has been identified in patients with epididymitis, although whether it was the actual causative agent is unclear. In patients with syphilis, infection can spread to the epididymis during the secondary phase. In homosexual men who engage in anal intercourse, coliforms also can lead to sexually transmitted epididymitis.[61]

In men older than 35 years, urinary tract pathogens become the predominant cause of epididymitis. *E. coli* is the most common, occurring in 32 to 55% in this age group.[60] *Pseudomonas aeruginosa* and *Proteus mirabilis* also can infect the epididymis, and although much less common in the industrialized world, *M. tuberculosis* also has been implicated. In immunocompromised patients, fungal and other opportunistic infections have been reported.

Unlike younger patients, older men with epididymitis tend to have urinary tract abnormalities that predispose them to these infections of the epididymis. In one review, over half of men older than 60 years with epididymitis had lower urinary tract obstruction.[62] Older men also are more likely to have undergone recent genitourinary instrumentation, another risk factor for epididymitis. This includes hernia repair, which often can lead to iatrogenic infection of the nearby spermatic cord and epididymis. Acute or chronic prostatitis also may increase the risk of epididymitis. Finally, several authorities have suggested a possible association between indwelling catheters and epididymitis. Each of these factors renders older men prone to epididymitis after they are no longer sexually active.

Epididymitis also occurs in children. Historically, epididymitis was considered uncommon in prepubertal children, but it has been increasingly identified in this age group.[63] In children, epididymitis is most commonly idiopathic, although children can also have congenital genitourinary anomalies that predispose them to recurrent infection. The most commonly associated abnormality is neurogenic bladder, which produces increased pressure during urination and reflex into the ejaculatory ducts. In contrast to older children, in infants, bacterial causes are more common.

Amiodarone also has been implicated as a cause of epididymitis, with nearly 20 case reports in the literature. One study has suggested that amiodarone-induced epididymitis may be more common, arising in as many as 3 to 11% of patients receiving this agent. The effect is dose dependent, typically occurring after at least 4 months of treatment and with doses of 400 mg or more per day.[64] Amiodarone concentrates in the testicle, resulting in lymphocytic infiltration and epididymal fibrosis. Unlike with infectious epididymitis, patients do not have fever, pyuria, or leukocytosis.

Clinical Features. Patients with epididymitis experience scrotal pain of gradual onset, prompting them to come to the ED later in the clinical course than patients with torsion, whose symptoms tend to be more abrupt in onset. Initially, this pain may reside in

www.ketabpezeshki.com 66485457-66963820

the lower abdomen or flank, caused by inflammation of the vas deferens. In patients with STDs, urinary symptoms and urethral discharge are found in 10 to 30%. Nearly three fourths of patients report fever.[65] In the early stages of the disease, tenderness is localized to the epididymis, but it quickly spreads to the ipsilateral testicle. Later in the course the scrotum can become edematous, erythematous, and extremely tender. Although Prehn's sign—decrease in pain with elevation of the scrotum—has been touted as indicative of epididymitis, it has low sensitivity and specificity. Similarly, only 10% of patients with epididymitis from sexually transmitted organisms have urethral discharge on examination. None of these historical factors or physical findings have been shown reliably to differentiate torsion from epididymitis.

Diagnostic Strategies. Urinalysis typically demonstrates evidence of infection, with the finding of pyuria in 50 to 93% of patients with epididymitis (defined as the presence of more than four leukocytes per high-power field).[66] If patients are at risk for STD, a urethral swab or urine sample should be obtained to test for *C. trachomatis* and *N. gonorrhoeae;* polymerase chain reaction (PCR) and other nucleic acid amplification tests have the greatest sensitivity and should be used when available. Studies suggest that this diagnostic regimen is underused, with less than 35% of adults with epididymitis undergoing testing for STDs.[67]

The literature also describes epididymal aspiration, but this diagnostic modality has no role in the ED. It is difficult to use, and studies suggest that all patients with positive epididymal cultures have positive urine cultures. Systemic leukocytosis may be present but is a nonspecific finding and does not differentiate epididymitis from torsion. In prepubertal children, urinalysis and urine culture rarely are positive; a retrospective review of 151 children with epididymitis demonstrated bacteriuria in only one patient.[68] Nevertheless, in these patients, urine cultures should still be obtained to rule out bacterial infection, because untreated bacterial infections may lead to long-term complications.

In patients with an equivocal presentation for epididymitis versus testicular torsion, testicular ultrasound examination should be performed in the ED as rapidly as possible. As noted earlier, historical and physical examination features and laboratory results cannot reliably distinguish torsion from epididymitis or other diseases. With inflammation, the epididymis appears enlarged and hypoechoic (Fig. 99-11). On color Doppler ultrasound images, the affected testicle will show increased vascularity. These findings are 70% sensitive and 88% specific for epididymitis and can help differentiate the condition from torsion.[69] However, a minority of patients with torsion have preserved flow that can appear similar to epididymitis. In these cases, the presence of a spermatic cord knot, indicative of torsion, should be sought.

Finally, prepubertal children with recurrent epididymitis should undergo renal ultrasound and cystography to identify any potential underlying urinary tract abnormalities. These are important to identify to reduce the risk of future inflammation.

Differential Considerations. Three intrascrotal processes are commonly confused with epididymitis: torsion, torsion of the testicular appendage, and tumor of the testicle. Epididymitis is the most common misdiagnosis in patients with torsion, and this error can lead to loss of the testicle.

Management. Empirical antibiotics should be selected in accordance with the patient's age, sexual history, and any previous genitourinary instrumentation (Table 99-7). In patients with a suspected sexually acquired infection, ceftriaxone 250 mg intramuscularly (IM) should be given to treat possible *N. gonorrhoeae* infection. In conjunction, doxycycline 100 mg PO twice daily for 10 to 14 days should be started to treat *C. trachomatis* or *Ureaplasma urealyticum* infection. Although this regimen has never been studied in patients with chlamydial epididymitis, it is presumed to be more successful than the single-dose azithromycin that is used for uncomplicated urethritis. Treatment of sexual partners should be arranged even if the partner's culture demonstrates no growth because female partners of men with epididymitis often harbor *C. trachomatis* infection, including partners of men with negative culture results. A recent retrospective review suggests that only 50% of patients 18 to 35 years of age receive appropriate antibiotic treatment for sexually transmitted causes of epididymitis.[67]

In patients with infection by urinary tract pathogens, ciprofloxacin 500 mg PO twice daily has been shown to be the most successful regimen, with 80% of patients cured after 14 days of treatment. Ofloxacin 200 mg PO twice daily for 14 days is an

www.ketabpezeshki.com 66485457-66963820

alternative that also will cover sexually transmitted organisms and therefore is the ideal treatment when it is unclear if a patient has sexually acquired or urinary tract pathogens. Treatment can later be adjusted in accordance with the results of the patient's urine culture. In addition to appropriate antibiotics, bed rest, scrotal support, analgesics, sitz baths, and ice packs may be beneficial. A urologist can block the spermatic cord with bupivacaine to provide pain relief. This maneuver also appears to hasten the healing process, perhaps by increasing blood flow to the spermatic cord that was anesthetized. On discharge the patient should be referred to a urologist for follow-up evaluation within 1 week.

In prepubertal boys in whom an idiopathic cause is suspected, antibiotics are not routinely recommended. This contrasts with prior teaching and practice; previously over 90% of boys received antibiotics.[69] Urine cultures should be obtained for these boys, and only if the cultures reveal bacteria should antibiotic therapy be initiated. This graduated treatment approach is supported by studies showing that most epididymitis in boys is idiopathic.[69] Boys should limit activity, elevate the scrotum with ice packs, and reduce inflammation with NSAIDs. In contrast, infants often have bacterial epididymitis and should be treated empirically with antibiotics pending urine culture results.

Typically, symptoms resolve in 2 weeks in patients with sexually acquired disease and in 4 weeks in patients with urinary tract pathogens.[61] Complications are more common in older men, occurring in 39% of patients, and include intratesticular and epididymal abscess, testicular infarction, and late testicular atrophy. In adolescents, infection often reduces spermatogenesis, but the long-term effect on fertility is unclear. Finally, prepubertal children are at risk for developing testicular abscess, necrosis, and infertility.[68]

Disposition. Patients with systemic signs of toxicity (fever, chills, nausea, vomiting) or complications of acute epididymitis should be hospitalized and treated with parenteral antibiotics. Well-appearing patients with uncomplicated epididymitis can be discharged from the ED and should be reassessed within 1 week to ensure that their symptoms are resolving. Spread of infection, continued scrotal edema, ongoing testicular pain, and scrotal wall fixation are indications that outpatient management has failed, and hospitalization and emergent urologic evaluation are required to rule out an alternate diagnosis such as testicular torsion or scrotal abscess. Prepubertal children with evidence of bacterial infection require outpatient urologic evaluation owing to a high incidence of genitourinary tract abnormalities.

Testicular Tumors

Perspective. Tumor of the testis is the most common malignancy in young men but accounts for only 1% of all cancers in men. These tumors are more common in infertile patients and whites. They also occur with increased frequency in the nondescended and descended testicles of patients with cryptorchidism. A number of simplified classification systems have been proposed for categorizing the different types of testicular tumors. Approximately 95% of tumors are germ cell tumors, with half of these being seminomas and the other half being mixed types, including teratomas, choriocarcinomas, and yolk sac tumors. The other 5% of testicular tumors are sex cord stromal tumors. The disease course will depend on the type of tumor present as well as the age of the patient.

Clinical Features. Unlike in torsion and epididymitis, patients with tumor typically have a painless scrotal mass. When pain develops, it most often is from acute hemorrhage within the tumor pushing against the nonpliable tunica albuginea. Presence of pain should be considered unusual with testicular tumor, and in such cases, torsion and epididymitis should be ruled out before a diagnosis of malignancy is considered. Unlike other painless scrotal masses, such as hydroceles and varicoceles, tumors cannot be separated from the underlying testicle. Palpable tumors are more likely to be malignant compared with tumors identified only with imaging. Patients with tumor also can have symptoms related to metastases from a previously undiagnosed testicular cancer; 15% of patients have metastases to regional lymph nodes at the time of diagnosis, and 5% have metastases to the abdomen or pelvis.

Diagnostic Strategies. All patients with a scrotal mass should undergo a scrotal ultrasound examination. This study can reveal a concomitant hydrocele or a homogeneous hypoechoic lesion. Intratesticular tumors are typically hypervascular with irregular branching vessels. Leydig cell tumors are unique, because they show hypervascularity around the lesion but no internal color Doppler flow. Although helpful for staging purposes, CT scans of the chest and abdomen are necessary in the ED only if the patient has complaints related to these parts of the body. Urinalysis findings typically are normal.

Management. Suspicion of a testicular tumor is an indication for urgent referral to a urologist because radical orchiectomy with high ligation of the spermatic cord may be required. The radiosensitive nature of seminomas renders the combined treatment of orchiectomy and radiation therapy highly successful for early-stage disease. The ultimate treatment strategy, however, should be determined by a urologist. Any patient with systemic symptoms should be admitted to the hospital.

Orchitis

Perspective. Orchitis is a rare acute infection of the testis. It is most common in prepubertal boys, with viral infections such as mumps causing a majority of cases. Orchitis rarely develops in prepubertal boys with mumps but is more common in adolescent males with mumps. It tends to arise several days after the onset of parotitis. Although vaccination has significantly reduced the incidence of mumps infection, sporadic outbreaks have occurred. Infections in vaccinated individuals are increasingly common, presumably resulting from vaccine failure or antigenic differences between the infecting and vaccine strains.

Owing to the testes' relatively high threshold of resistance to infection, bacterial orchitis more commonly results from local bacterial spread from the epididymis. The most frequent bacterial pathogens are *N. gonorrhoeae, C. trachomatis, E. coli, Klebsiella,* and *P. aeruginosa.* These organisms tend to infect postpubertal males and men older than 50 years with benign prostatic hypertrophy (BPH).

Clinical Features. A patient with mumps orchitis has testicular pain and swelling that commonly begins 4 to 6 days after the onset of parotitis, although it can develop in the absence of parotitis. The clinical course varies, with adults having more severe symptoms. Clinical resolution generally occurs in 4 to 5 days. More than 50% of testes involved with mumps orchitis develop atrophy; however, this seldom results in infertility.

Patients with bacterial orchitis have fever and scrotal pain. They often have constitutional signs and symptoms including nausea, vomiting, myalgias, and malaise. The affected testicle (the disease is unilateral in 70% of patients) and the scrotum are swollen, tender, and erythematous.

Diagnostic Strategies. As with all causes of scrotal pain, the first priority is to exclude testicular torsion. If the patient clearly has mumps orchitis based on the clinical presentation and a history of preceding parotitis, then no other tests are necessary. For all other patients, urinalysis and urine culture should be performed. Patients in whom the diagnosis is unclear also should undergo color Doppler ultrasound examination to evaluate for torsion or concomitant epididymitis. On ultrasound, orchitis shows hypervascularity, commonly described as a "testicular inferno." Blood

www.ketabpezeshki.com 66485457-66963820

tests are typically not helpful, as false negatives are common with serologic testing, particularly in vaccinated individuals.

Management. In sexually active patients, ceftriaxone and doxycycline should be used as in epididymitis to cover *N. gonorrhoeae* and *C. trachomatis.* In older patients, fluoroquinolones provide the best coverage of gram-negative organisms. Treatment of viral orchitis is supportive only. Although steroids may improve symptoms, they can reduce testosterone levels. All patients should receive local scrotal care as described for epididymitis. Patients with marked pain, high fever, or constitutional symptoms merit hospitalization and parenteral antibiotics.

Testicular Trauma

The most concerning injury associated with trauma involves rupture of the testicle. The presentation can range from a large blood-filled scrotum to minimal swelling with mild pain of the testicle. If there is any concern for rupture, scrotal ultrasound is indicated. Disruption in the echogenic tunica albuginea is 100% sensitive and 65% specific for rupture.[70] Surgical intervention is associated with higher rates of testicular salvage. Hematomas can also form in the testicle without overt rupture. Similar to rupture, these require surgical evaluation unless the tunica albuginea is intact. Trauma can also result in formation of a hematocele with blood accumulating within the tunica vaginalis. This often leads to ecchymosis of the scrotal wall. Ultrasound can also identify this condition. Lacerations of the scrotum that do not violate the dartos fascia can be repaired in the ED.

Inguinal Hernia, Acute Hydrocele, Varicocele, and Spermatocele

Inguinal hernias, hydroceles, varicoceles, and spermatoceles are reasonable considerations in the differential diagnosis of an acute scrotal mass. These clinical entities are typically painless and readily identifiable on physical examination. Most children with inguinal hernias will not have any palpable mass on examination but will report a history of intermittent bulge in the groin that appears with straining or crying. Less commonly an inguinal mass is palpable, and it may extend into the scrotum. If this mass becomes incarcerated, it will be tender, and often the overlying skin will be edematous and erythematous. Children typically will develop irritability, vomiting, or abdominal distention. Incarcerated hernias should be reduced promptly to prevent bowel infarction from strangulation. Reduction can be accomplished by applying gentle pressure to expel the gas and stool in the bowel from the hernia. Pressure is then applied over the distal aspect of the hernia to reduce the bowel. If this technique fails, which is more likely in younger children with prolonged symptoms, then the patient should be placed in the Trendelenburg position, ice applied to the groin, and surgery consulted. After reduction of an incarcerated hernia, children typically require hospitalization and delayed surgical repair. In contrast, acute hydroceles typically are benign, are localized to the scrotum, and transilluminate. Varicoceles are enlarged spermatic cord veins that typically are painless or cause only minimal discomfort. On examination, they are often described as feeling similar to "a bag of worms" just superior to the testicle and decrease in size when the patient is supine. In contrast, a spermatocele is a sperm-containing cyst that is palpated as a nontender mass posterior to the testicle. Ultrasound is diagnostic of both conditions. No emergent treatment is necessary, but patients require outpatient urologic evaluation.

Regardless of the cause of the scrotal swelling, it remains crucial to rule out concomitant pathology by assessing the testicle thoroughly, as each of these conditions is often identified in patients with torsion, epididymitis, and tumors.

ACUTE URINARY RETENTION

Perspective

Acute urinary retention (AUR) is the sudden inability to pass urine voluntarily. In contrast to patients with anuria, in which the kidneys fail to produce urine, patients with AUR have normal renal function but cannot pass urine and typically have a distended bladder. The lifetime risk of AUR increases with age: 10% of men in their 70s and 33% of men in their 80s have experienced AUR.[71] The retention most commonly is secondary to an obstructive lesion but also can be the presenting manifestation of other pathologic processes (Box 99-6). For example, in women it often develops from infrequent voiding leading to an atonic bladder. In younger patients, it often is suggestive of a serious underlying neurologic disease.

The most common cause of AUR seen in the ED is obstruction of the urinary tract distal to the bladder. In men, BPH is the typical precipitant, causing AUR in 53% of patients.[72] Enlargement of the prostate coupled with constriction of the prostatic urethra from heightened alpha-adrenergic tone obstructs urinary output. Prostate cancer also can block the urethra by means of similar mechanisms, and urinary retention develops in 70% of patients with this cancer. Approximately 25% of men seen in the ED with AUR have prostate cancer, and often this cancer diagnosis was not known beforehand.[73] Strictures of the urethra can arise after trauma from manipulation with a Foley catheter, cystoscopy, previous infections, or radiation therapy. Such strictures may then lead to obstructed urinary outflow. Other, less common obstructive causes of AUR include phimosis (inability to retract the foreskin over the glans penis) and paraphimosis (inability to reduce the foreskin over an edematous glans).

In women, the most frequent causes of obstructive AUR are pelvic masses and prolapse of pelvic organs such as the bladder, rectum, or uterus. These structures compress the urethra, thereby creating AUR. In both sexes, bladder neoplasms, fecal impaction,

Table 99-8 Presentation and Diagnosis of Acute Urinary Retention

CAUSE	HISTORY	PHYSICAL EXAMINATION FINDINGS	DIAGNOSIS*
Benign prostatic hypertrophy	Frequency, urgency, hesitancy Prior retention	Enlarged, firm prostate	UA
Prostate cancer	Frequency, urgency, hesitancy Previous retention Constitutional symptoms	Enlarged, firm prostate Nodular prostate	UA
Phimosis, paraphimosis	Penile pain	Nonretractable foreskin Edematous penis	Clinical only
Prostatitis	Dysuria, frequency, urgency Fever, chills	Warm, tender, boggy prostate Penile discharge	UA Urine culture
Urethritis, vulvovaginitis	Dysuria, frequency, urgency Itching	Discharge	UA Urine culture Urethral or cervical culture
Pelvic mass	Pelvic pain pressure	Prolapse of rectum, bladder, uterus	UA Ultrasound imaging, CT
Neurogenic bladder	Other neurologic complaints	Neurologic deficits	UA CT, MRI

CT, computed tomography; *MRI,* magnetic resonance imaging; *UA,* urinalysis.
*In the emergency department setting, each of these diagnoses is made primarily by the history and findings on the physical examination. Additional tests are needed as described.

GI masses, foreign bodies, or stones can block urine outflow. Finally, congenital posterior urethral valves are the most common source of AUR in children.

Infection also can cause AUR and should be considered in the differential diagnosis, because treatment of the condition through placement of a catheter will correct the retention but not the underlying infection. The most common infectious causative disorder is acute prostatitis, which usually is a result of infection of the prostate by *E. coli* or *P. mirabilis.* The resulting edema causes AUR, particularly in the setting of BPH or other underlying prostatic disease. Similarly, urethritis from a UTI or sexually transmitted infection can obstruct the urethra, and in women vulvovaginitis also can produce enough urethral edema to create AUR. In Elsberg syndrome, genital herpes involving the sacral nerves leads to AUR. Finally, in pediatric patients UTIs can induce sufficient dysuria that the child refuses to void, with consequent urinary retention.

Pharmacologic agents have been associated with AUR. Anticholinergic agents inhibit detrusor muscle contraction, whereas sympathomimetic agents increase α-adrenergic tone in the prostate. In addition, NSAIDs may inhibit prostaglandin-mediated detrusor muscle contraction, leading to a twofold increase in risk of AUR in men taking these drugs.[74]

Although less common in older patients, neurogenic causes of AUR constitute an important etiologic category. Upper motor neuron lesions create bladder spasticity through a deficit above the micturition center in the sacral cord. They result from spinal cord and cortical lesions caused by multiple sclerosis, trauma, Parkinson's disease, stroke, or neoplasms. Lower motor neuron deficits produce bladder flaccidity with lesions below S1. Such lesions typically are associated with spinal cord tumors, epidural abscesses, spinal trauma, Guillain-Barré syndrome, tabes dorsalis, and multiple sclerosis. Peripheral nerve lesions also can cause AUR. Diabetic peripheral neuropathy is the most commonly encountered peripheral lesion and occurs in 45% of patients with diabetes mellitus.[75]

Numerous alternate causes for AUR are recognized, as listed in Box 99-6. They include intervertebral disk herniation, recent surgery, and psychogenic causes. In the ED these are encountered much less frequently than the aforementioned disorders. Psychogenic urinary retention also is rare and is a diagnosis of exclusion made only after appropriate studies of bladder function have been performed by a urologist.

Box 99-7 Symptoms of Urinary Retention

Obstructive Symptoms

Urinary hesitancy
Straining to void
Decrease in size and force of urinary stream
Interruption of urinary stream
Sensation of incomplete emptying
Previous episode of urinary retention

Irritative Symptoms

Urinary frequency
Urinary urgency
Dysuria (usually secondary to infection)
Nocturia or nocturnal incontinence

Adapted from Lapides J: Fundamentals of Urology. Philadelphia, WB Saunders, 1976.

Clinical Features

Although the potential causes of AUR are many, the history and physical examination can considerably narrow the scope of the differential diagnosis (Table 99-8). Patients with AUR report sudden pain and have a distended bladder that is tender to palpation (Box 99-7). With lesions proximal to the bladder, patients typically note pain in the flank, whereas lesions distal to the bladder can produce pain radiating to the scrotum or labia. This pain is often quite severe, leading to significant distress. By contrast, with slowly developing or chronic obstructions, patients typically are older with multiple comorbid conditions; they have overflow incontinence and report little to no pain.

When obstruction is the cause of AUR, the patient often will recall multiple previous episodes of urinary retention. In addition to this history, patients with BPH report frequency, urgency, hesitancy, nocturia, difficulty initiating the urinary stream, decreased force of the stream, a sensation of incomplete voiding, and terminal dribbling. The prostate is enlarged, firm, and non-nodular.

www.ketabpezeshki.com 66485457-66963820

Normal findings on the prostate examination do not exclude BPH. Patients with prostate cancer can have similar symptoms, but these often are accompanied by weight loss, bone pain, and other constitutional signs and symptoms. These patients generally will have an enlarged, nodular prostate. Examination of the penis also is crucial in men because phimosis will reveal edema of the penis with a nonretractable foreskin. In women with obstruction, pelvic pain and pressure are symptoms commonly associated with AUR. A prolapsed bladder, rectum, or uterus and enlarged ovaries or uterus can be identified on pelvic examination.

Patients with an infectious cause for their symptoms often complain of dysuria, frequency, urgency, hematuria, fever, chills, and low back pain. In acute prostatitis these symptoms can be associated with penile discharge and a tender, warm, and boggy prostate. Despite the obstruction, the patient may nevertheless be able to void small amounts of urine. In vulvovaginitis and urethritis, presenting complaints also may include discharge and pruritus.

Patients with a neurogenic cause for AUR may already have a history of neurologic disease. They require a thorough neurologic examination, focusing on strength, sensation, and reflexes in the lower extremities, for which innervation is similar to that of the bladder. The status of the bulbocavernosus reflex, anal reflex, sphincter tone, and perineal sensation also should be assessed.

Diagnostic Strategies

The only two suggested procedures in the ED for AUR are placement of a Foley catheter and a urinalysis. The urinalysis can reveal infection, whereas presence of hematuria suggests infection, tumor, or calculi. Patients with hematuria require follow-up because the bleeding can arise from prostatic obstruction alone or may have other, more serious causes such as bladder cancer. A basic chemistry panel for assessment of renal function should be obtained only when renal damage or hydronephrosis is a concern. Historically, it was believed that the significant pain associated with AUR prompts patients to come to the ED readily before their creatinine elevates. However, a recent study of patients in the ED with AUR revealed that 24% of patients had an elevated creatinine on presentation and 7% had persistent elevations 1 month later.[76]

Imaging studies are indicated when patients have evidence of concomitant infection or neurologic deficits or when the diagnosis of AUR is unclear. With an equivocal history or physical examination, bedside ultrasound can confirm AUR. Renal and bladder ultrasound studies provide visualization of any obstruction, hydronephrosis, or other causes of upper urinary tract disease. Pelvic ultrasound examination and CT scan evaluate for masses or malignancy causing obstruction. Magnetic resonance imaging of the spine evaluates for disk herniation, cord compression, and cauda equina syndrome. Cystoscopy and retrograde cystourethrogram can depict problems in the lower urinary tract and usually are performed as outpatient procedures.

Several other tests described in the literature provide little benefit in the ED management of patients with AUR. Prostate-specific antigen (PSA) levels frequently are elevated in the setting of AUR, so a PSA assay will not help in differentiating cancer from other causes of retention. Similarly, alternate imaging modalities have rendered IVP unhelpful in the ED.

Management

Immediate placement of a 14F to 18F Foley catheter should provide decompression of the bladder. If this fails, placement of an elbowed catheter (coudé catheter) should be attempted; its curved and firm tip allows it to pass more easily across any obstruction. The curved tip of the coudé catheter should point cephalad during insertion. If both of these techniques prove to be unsuccessful, a urologist should be consulted unless the ED personnel are well versed in the use of filiforms, followers, and metal sounds because such instrumentation without the requisite degree of skill may result in serious tissue damage. In addition, if a patient recently underwent urologic surgery, urethral catheterization should not be performed.

When immediate bladder decompression is required and a urologist is not available or major urethral trauma is present, suprapubic bladder drainage should be performed. With use of ultrasound guidance and sterile technique, a 22-gauge spinal needle should be inserted two fingerbreadths above the symphysis pubis in the midline and directed toward the anus. This needle can be used to administer local anesthetic and should be advanced until urine is aspirated. Return of air suggests that the needle is in the bowel, and the needle should be retracted and moved more cephalad. Once the bladder has been located, the needle is left in place and the syringe is removed. A guidewire is then passed through the needle into the bladder, followed by removal of the needle. A 1-cm skin incision is made, and a dilator and sheath are inserted into the bladder. The guidewire and dilator are removed, and a Foley catheter can then be passed through the sheath. The Foley balloon is inflated and urine drained (Fig. 99-12). Alternatively, an open technique with a trocar can be used. Finally, bladder aspiration without placement of a catheter can also be performed as a temporizing measure pending urology consultation.

Historically, it has been recommended that initial drainage be limited to 1 L to prevent postobstructive diuresis and hypotension. Such postobstructive diuresis is uncommon after AUR. Moreover, limited drainage of the bladder can increase the risk of UTI. Therefore, complete drainage should be performed.

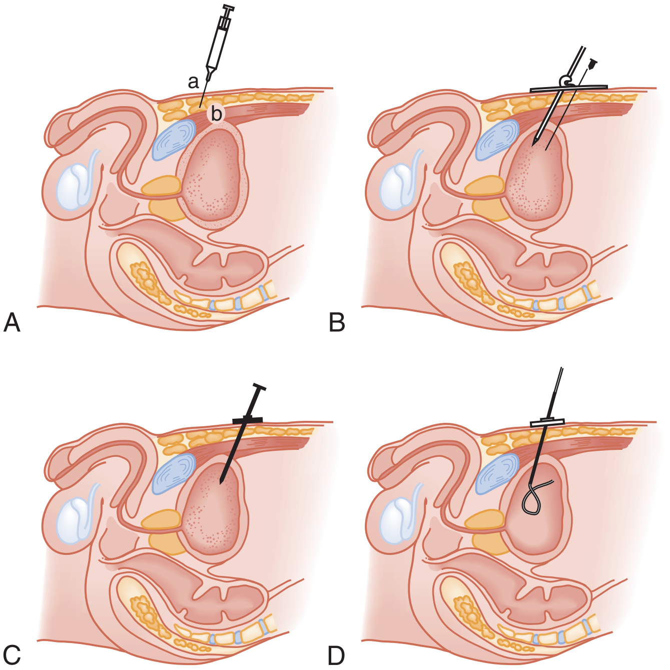

Figure 99-12. Cystostomy tube placement. **A,** Anesthetizing trocar tract. After a skin wheal *(a)* is raised, the suprapubic tract for the trocar is anesthetized, including the rectus fascia *(b)*. Anesthetizing until the bladder is penetrated will ensure total comfort for the patient during insertion of the trocar. **B,** Needle localization of the bladder. A spinal needle may be used even during insertion of the trocar to locate the bladder. **C,** Trocar position. The trocar is advanced until its sheath, as well as the point, is fully in the bladder. **D,** Tubing position. Enough tubing is inserted that it will not pull out of the bladder when the bladder empties. (From Robert JR, Hedges JR: Clinical Procedures in Emergency Medicine. Philadelphia, WB Saunders, 1985.)

www.ketabpezeshki.com 66485457-66963820

Complications

Catheterization has been associated with urethritis, cystitis, prostatitis, bacteremia, and sepsis. These infections are most common in patients with indwelling catheters and elderly debilitated female patients. For each day a catheter remains in place, there is an additional 4% risk of bacterial colonization of the bladder. Placement of a catheter also has been reported to cause postobstructive diuresis and hematuria. Such problems are believed to be related to rapid bladder decompression, so historically, gradual decompression has been recommended to prevent complications such as hematuria, hypotension, and postobstructive diuresis. Although hematuria occurs in 2 to 16% of patients after rapid bladder emptying, no major consequences from this bleeding have been documented.[77] Similarly, postobstructive diuresis can cause transient hypotension, but it is responsive to fluid administration. The side effects of rapid bladder decompression are rare; therefore all patients with AUR should undergo rapid, complete decompression of the bladder.

Rarely, chronic obstruction may lead to development of a salt-wasting nephropathy that requires treatment. The patient's urine output should be observed for 4 hours after catheterization. If output is greater than 200 mL/hour, the patient should be hospitalized for monitoring of blood pressure and sodium concentration.

Disposition

After bladder drainage, healthy and reliable patients can be safely discharged from the ED with an indwelling catheter and education about catheter management. Follow-up with a urologist should be arranged before the patient leaves. Patients with concomitant infection, significant comorbid illnesses, impaired renal function, neurologic deficits, or complications from catheterization require emergent urology consultation and probably admission.

Although the catheter is an inconvenience for the patient, and chronic use has been associated with UTI, trauma, stones, and urethral strictures, early removal of the catheter also is associated with heightened risk for recurrence of AUR. In a study of patients with suspected BPH, if the bladder was drained and a catheter was not left in place, recurrent AUR developed in 70%.[78] In patients in whom the catheter remained in place for 3 days, AUR developed in 49%, and when the catheter was in place for 7 days, AUR recurred in only 38% of patients.[79]

Studies also suggest that initiation of an alpha-adrenergic blocker, such as tamsulosin, at the time of catheter insertion improves the likelihood of spontaneous voiding after catheter removal. In addition, a recent Cochrane review suggests that alpha-blockers may also improve the likelihood that a patient will not require ongoing catheter placement; 48 to 62% of patients on alpha-blockers successfully completed a trial without a catheter, compared with 23 to 28% of patients not treated with alpha-blockers.[80] These medications should be provided only after consultation with the urologist or primary care physician because they increase the risk of orthostatic hypotension, particularly in the elderly. 5-Alpha-reductase inhibitors, another medication typically used for BPH, have not been shown to reduce recurrence of AUR.[81]

Prophylactic antibiotic therapy is not recommended in patients with AUR because although bacteriuria often develops in patients with indwelling catheters, it typically is asymptomatic. Antibiotics only promote resistance among these organisms.

Definitive therapy often requires surgical correction of any underlying obstruction. This should not be performed in the acute setting, as early surgery is associated with increased morbidity.

HEMATURIA

Perspective

Although hematuria is commonly encountered in the ED, the specific underlying disorder often is elusive. Most cases seen in the ED result from detection of asymptomatic microscopic hematuria, as an incidental finding noted on routine examination through microscopic or dipstick analysis of the urine. The bleeding typically is transient and not indicative of serious underlying pathology. After an uneventful workup, patients often are referred for outpatient evaluation; however, the cause of the hematuria remains unknown in 61% of patients evaluated with laboratory and imaging studies.[82] Less commonly, patients come to the ED complaining of gross blood in their urine. Unlike microscopic hematuria, gross blood in the urine often is the presenting symptom of an underlying malignancy. The risk of malignancy is greater in older patients; in those older than 60 years, gross hematuria has a positive predictive value for malignancy of 22.1% in men and 8.3% in women.[83] Regardless of age or visibility of blood in the urine, patients with hematuria require evaluation in the ED to rule out life-threatening diagnoses such as malignancy and abdominal aortic aneurysm.

Principles of Disease

Blood in the urine can be gross or microscopic. As little as 1 mL of whole blood in 1 L of urine can produce gross hematuria, turning the urine red. Multiple other substances and reactions can turn the urine red, and centrifugation of the urine and microscopic analysis differentiate these false positives from true hematuria. After centrifugation, the red color persists only in the urine sediment with hematuria. By contrast, a red supernatant appears bloody but contains no RBCs on microscopic analysis, and the cause typically is a benign condition (Box 99-8). The supernatant should be tested for heme, and if positive suggests hemoglobinuria or myoglobinuria. The supernatant will then contain heme in addition to a red coloring agent.

Microscopic hematuria is the presence of more than three to four RBCs per high-power field in clear urine. The particular cutoff for number of RBCs per high-power field used is arbitrary. Lower numbers of RBCs per high-power field decrease specificity but increase sensitivity, because significant disease can occur with as little as one RBC per high-power field. Urine dipstick testing increases sensitivity to 91 to 100% for the presence of blood, detecting one or two RBCs per high-power field. A negative urine dipstick rules out the presence of hematuria, and urine microscopy is then not necessary. However, the dipstick is less specific, with false positives occurring when sperm are present and with alkaline or extremely concentrated urine.[84] Accordingly, a positive result on urine dipstick testing should trigger at least reflex confirmation with microscopic analysis.

Bleeding from anywhere along the genitourinary tract can produce hematuria. In both the upper and lower portions of the urinary tract, infection, trauma, and renal calculi are the most

UTI, urinary tract infection.

common causative disorders. Patients also can have more serious causes of hematuria, such as malignancy or vascular lesions (e.g., abdominal aortic aneurysm), and these diagnoses should be excluded. Unfortunately, hematuria has poor specificity for malignancy; an analysis of 156,691 adults with hematuria revealed malignancy in only 0.7% of patients.[85] Malignancy was more common in patients older than 40 years (odds ratio [OR] 17), male patients (OR 4.8), and patients who had more than 25 RBCs per high-power field (OR 4.0). Other, less common risk factors for malignancy include cigarette smoking, occupational exposure to chemicals such as aniline dye and benzidine, and excessive use of analgesics. When another cause for the hematuria, such as UTI or stone, is identified in the ED, close follow-up is still necessary because patients with these risk factors often prove to have an underlying malignancy. In the upper urinary tract, the glomerulus is the most frequent source of bleeding, which may result from glomerulonephritis, immunoglobulin A (IgA) nephropathy, or nephritis. The common causes of hematuria are further divided by patient age and gender in Box 99-9.

Occasionally, hematuria also has been attributed to warfarin use, BPH, and exercise. Supratherapeutic anticoagulant therapy can lead to blood in the urine, but therapeutic anticoagulation does not produce spontaneous hematuria. The incidence of hematuria was not significantly different between controls and 243 patients followed prospectively while receiving warfarin.[86] Similarly, BPH can lead to increased vascularity of the prostate but does not increase the risk of hematuria. High-intensity exercise also can produce hematuria. This bleeding typically is transient and clinically inconsequential. However, a concomitant genitourinary tract lesion can be present, particularly if the bleeding persists for more than 72 hours after exercise. Because warfarin use, BPH, and exercise do not directly cause persistent hematuria, patients in whom these factors are present require evaluation identical to that for other patients.

Table 99-9 Timing of Blood Appearance during Micturition and Disease Location

TIMING OF BLOOD APPEARANCE	LOCATION OF LESION
Beginning of micturition	Urethra
Between episodes of urination	Urethral meatus Distal urethra
End of micturition	Bladder Prostatic urethra
Throughout urination episode	Bladder Ureter Kidney

In children, gross hematuria typically arises from UTI or benign causes such as irritation of the urethral meatus or hypercalciuria without nephrolithiasis.[87] However, when accompanied by trauma, edema, or hypertension, more serious causes should be considered such as rhabdomyolysis, tumors, glomerulonephritis, and hemolytic uremic syndrome.

Clinical Features

The timing and appearance of the blood in the urine can help narrow the scope of the differential diagnosis (Table 99-9). Repeated episodes of bleeding during and after menstruation in women suggests endometriosis of the urinary tract. Gross hematuria suggests lesions in the lower urinary tract. Passage of clots indicates a source below the kidney. Finally, passage of a large amount of congealed blood in the urine suggests malignancy of the kidney.

Several other historical factors also are associated with particular causes of hematuria (Box 99-10). A careful history will identify a benign cause for hematuria, such as menstruation, recent heavy exercise, or sexual activity, as well as the use of agents that can produce red urine without blood (see Box 99-8). Patients may report frequency, urgency, and dysuria in the setting of infection. They may note flank pain with urolithiasis or pyelonephritis. IgA nephropathy arises days after a viral respiratory infection, whereas poststreptococcal glomerulonephritis develops in children 1 to 2 weeks after skin or throat infections.

The physical examination is crucial in establishing the diagnosis. Hypertension occurs with glomerulosclerosis and, in the setting of peripheral edema, suggests nephrotic syndrome. Atrial fibrillation increases the likelihood of embolic disease and renal infarction. An abdominal bruit may be caused by an arteriovenous fistula, whereas a palpable abdominal mass may represent an abdominal aortic aneurysm. Flank pain and tenderness can arise with pyelonephritis or nephrolithiasis. The external genital examination can show evidence of trauma or a tumor, and in children often a reveals a rectal or vaginal source for the bleeding, such as urethral prolapse. It is also important to assess for hypertension and edema in children, which can arise with nephritis.

Diagnostic Strategies

A clean-catch or catheterized urine specimen should be obtained in all patients with hematuria. Catheterization itself induces hematuria in approximately 15% of patients, but the amount of bleeding is inconsequential, rarely exceeding three RBCs per high-power field.[88] Bedside urine dipstick testing of this urine should be performed. If positive for blood, then urine microscopy should be performed. Microscopy will reveal WBCs in addition to RBCs in the presence of infection. Proteinuria and RBC casts are seen with glomerular disease, and the urine is often brown or cola colored. Patients with these disorders do not require further

Box 99-10 Medical History for Patients with Hematuria

- Exclude pseudohematuria—drugs, vegetable dyes, pigments
- Factitious—Munchausen syndrome, narcotic-seeking behavior
- Bleeding diathesis
- Clots—indicate nonglomerular bleeding; large, thick clots (bladder); small, stringy clots (upper tract)
- Gross hematuria—relationship to exercise, infection
- Relationship of gross hematuria to urinary stream—initial (urethra distal to the urogenital diaphragm), total (bladder proper or upper urinary tract), terminal (bladder neck or prostatic urethra)
- Painful hematuria—urinary tract infection or calculus, papillary necrosis, passage of clots, obstruction, loin pain—hematuria syndrome, glomerulonephritis
- Genitourinary history—flank trauma or pain frequency; nocturia; dysuria; previous stones, tissue passage, or infections; vaginal or penile discharge; sexual activity; presence of urinary catheter
- Relationship to menstruation—endometriosis
- Sickle cell disease or trait
- Medications
- Systemic symptoms—fever, rash, joint pain, weight loss
- Infectious cause—night sweats, sore throat, impetigo, recent tooth extraction or other invasive procedure, diarrhea, travel to areas endemic for *Schistosoma haematobium*
- Risk factors for urologic cancer—age older than 40 years, tobacco use, analgesic abuse, pelvic irradiation, cyclophosphamide, *S. haematobium,* occupational exposure to dyestuffs and rubber compounds
- Family history—hematuria, renal disease, sickle cell disease, deafness, bleeding diathesis
- Previous testing—blood pressure, urinalysis, serum chemistries, intravenous pyelogram
- Pregnancies—proteinuria, hypertension (with month of onset)

evaluation in the ED beyond the urinalysis and should be referred to a nephrologist. The exception is glomerular disease in children, which can produce substantial elevations in blood pressure and pulmonary edema with glomerulonephritis or anemia, thrombocytopenia, and renal failure with hemolytic uremic syndrome.

By contrast, any patients with gross hematuria or microscopic hematuria with risk factors for significant disease require thorough evaluation before discharge from the ED (Box 99-11). Renal function should be assessed to rule out the development of renal insufficiency. They also should undergo appropriate imaging tests, although clear consensus is lacking on the appropriate radiographic study. If findings fail to suggest a particular disorder as a cause for the hematuria, a CT scan with contrast or a renal ultrasound study should be performed. If the possibility of an occult stone is a concern, the CT scan should be ordered without contrast. CT scanning is highly sensitive for stones, masses, and other diseases of the upper urinary tract.[89] If contrast CT must be avoided owing to pregnancy, renal insufficiency, or a history of anaphylaxis to contrast medium, then ultrasound imaging is the modality of choice. Ultrasound is less sensitive than a CT scan for detecting stones, small masses, and traumatic causes of hematuria. Although it is not as sensitive as IVP for identifying lesions of the bladder and ureters, ultrasound does provide adequate visualization of the kidney. Ultrasound is the recommended imaging study in children with atraumatic hematuria because there is no radiation exposure and malignancy is less common.

CT is the appropriate imaging modality for both adults and children with traumatic hematuria. Its sensitivity and specificity exceed those of ultrasound. The exact level of hematuria that should trigger imaging is unclear, but it appears that patients without gross hematuria or evidence of coexisting abdominal or pelvic injuries are unlikely to have clinically significant injuries on CT.[90] In patients with hematuria and pelvic fractures, CT cystogram should also be performed to evaluate for bladder injury. In patients with blood at the urethral meatus or straddle injuries, a retrograde urethrogram should be obtained to evaluate for urethral injury. Historically, IVP was commonly used for the evaluation of hematuria in trauma, but its use now should be limited to unstable patients in whom CT is impractical.

IVP, angiography, retrograde pyelography, and cystoscopy should be reserved for outpatient evaluations, when diagnostic imaging in the ED with ultrasonography or CT shows no evidence of disease. Finally, urine cytology can increase the sensitivity of the diagnostic evaluation, particularly for bladder cancer.

Disposition

Patients younger than 40 years, with no risk factors for severe disease and an ED workup not revealing of a particular cause for their microscopic hematuria, can be discharged with outpatient follow-up to ensure resolution of the hematuria. Such transient hematuria is most commonly idiopathic but also can arise with infection, trauma, and exercise. By contrast, patients with known risk factors or gross hematuria require imaging in the ED. If findings on a subsequent workup are negative, urgent outpatient evaluation is essential because within 3 to 4 years a genitourinary malignancy will develop in 1% of older patients with initially negative findings on workup.[91]

KEY CONCEPTS

- Acute scrotal pain should be considered a result of testicular torsion until proven otherwise.
- No historical or physical examination findings accurately and reliably exclude testicular torsion, and therefore patients with concern for this diagnosis should undergo a scrotal ultrasound.
- Sexually active males should receive ceftriaxone and doxycycline to treat epididymitis, whereas in young children, antibiotics are not typically required.
- Scrotal pain or swelling after trauma warrants a scrotal ultrasound to evaluate for testicular rupture.
- Patients with acute urinary retention and concomitant infection or neurologic deficits warrant imaging in the ED.
- Patients with acute urinary retention should have complete drainage of the bladder performed via catheterization or, if this is not possible, by suprapubic bladder aspiration.

Chapter 100

Selected Gynecologic Disorders

Carrie D. Tibbles

PERSPECTIVE

Many women come to the emergency department (ED) with either pelvic pain or vaginal bleeding. After the possibility of pregnancy has been eliminated, a primary goal of the ED evaluation is to recognize the presence of a few conditions, such as ovarian torsion, also known as *adnexal torsion,* that warrant urgent intervention and others, such as new postmenopausal uterine bleeding, that require reliable outpatient follow-up. Most patients also benefit from relief of symptoms and reassurance. This chapter specifically addresses the ED management of ovarian torsion, ovarian cysts, abnormal uterine bleeding, and the provision of emergency contraception. Vaginal bleeding and pelvic pain in pregnant patients and gynecologic infections are discussed in other chapters.

OVARIAN TORSION

Principles of Disease

Ovarian torsion accounts for approximately 3% of gynecologic emergencies.[1] While ovarian torsion can occur in young girls[2] and is increasingly recognized in postmenopausal women, it is still most common in the reproductive years because of the regular development of a corpus luteal cyst during the menstrual cycle.[3] Ovarian torsion is typically caused by a twisting of both the ovary and the fallopian tube on the vascular pedicle.[4] Most cases of torsion (50-80%) are associated with an ovarian tumor, typically a benign neoplasm; with large, heavy cysts, as seen in ovarian hyperstimulation syndrome after in vitro fertilization; or with polycystic ovaries.[1] Torsion may be a complication of pregnancy.[5,6] Torsion of a normal ovary only rarely occurs.[7] A slight predominance of ovarian torsion on the right side has been noted. The reason for this predilection is unclear but may relate to the stabilizing effect of the sigmoid colon on the left side.[4] In ovarian torsion, venous and lymphatic obstruction occurs initially, with subsequent congestion and edema of the ovary, progressing to ischemia and necrosis and eventual infarction of the ovary[1] (Fig. 100-1). Thrombosis of the ovarian vein and artery can occur as well. The ovary is often salvageable if the diagnosis is made before thrombosis occurs.[4] Because of the dual blood supply of the ovary from both the uterine and ovarian arteries, complete arterial obstruction is rare[7] (Fig. 100-2).

Clinical Features

Ovarian torsion can often be challenging to diagnose, because the classic symptoms of severe, sharp unilateral abdominal pain and nausea may not be present.[5,6,8,9] The presence of known risk factors for ovarian torsion such as an ovarian mass or infertility treatments may suggest the diagnosis.[1] Because the presentation can be variable and often subtle, the diagnosis can be difficult to make. In 87 patients with surgically confirmed torsion, the diagnosis was missed on the first visit in almost half of the patients. Patients reported pain from several hours to weeks in duration, most likely from intermittent ischemia, and almost all had some pain on abdominal palpation. Nausea was a symptom in many of the patients. Other series report similar findings.[2-4,6,8]

Diagnostic Strategies

Laboratory Tests

No specific laboratory tests are helpful in the evaluation of a patient for suspected ovarian torsion, except for a pregnancy test to exclude ectopic pregnancy. A small percentage of patients may have an elevated white blood cell count above 15,000/μL,[5] but this is not a reliable indicator of ovarian torsion.[5,8]

Imaging

Ultrasonography. Ultrasound examination is the initial imaging test in the evaluation of patients with pelvic pain suggestive of ovarian torsion.[7] Enlargement of the ovary is the most common ultrasound finding,[4] but the ovary also may have an abnormal position relative to the uterus. Enlargement of an ovary with a heterogeneous stroma and small, peripherally displaced follicles is the classic ultrasound appearance of torsion but is often absent, particularly early in the presentation[4] (Fig. 100-3). The ultrasound study may reveal a mass in the ovary or evidence of hemorrhage[10] (Fig. 100-4). The ultrasound appearance of ischemia can vary depending on the duration of the symptoms.[11] Free pelvic fluid also may be seen.[7] Hemorrhagic cysts and non-neoplastic masses frequently are associated with torsion. These may have a fluid-filled cystic component, exhibit a complex pattern with debris and septations, or be visualized as a solid mass.[10] The characteristic appearance of torsion may be difficult to appreciate if the ovary is obscured by an associated mass.[7]

Doppler Ultrasound Examination. Doppler ultrasound findings are inconsistent in ovarian torsion.[7,12,13] Many cases of surgically proven torsion will have documented blood flow on Doppler examination because the ovary has a dual blood supply from both the ovarian and uterine arteries. Because the torsion may be intermittent, the findings may also vary depending on the time of the examination.[7] If a large mass is present, the examination may be technically difficult to perform.[9] Despite these limitations, the Doppler examination is still useful because detection of abnormal venous flow is particularly important in early cases of torsion[10]

www.ketabpezeshki.com 66485457-66963820

(Fig. 100-5). Visualization of the twisting of the pedicle and the coiled vessels is referred to as a "whirlpool sign."[14,15] Lee and colleagues report an 88% accuracy for torsion when the twisted pedicle or whirlpool sign is visualized.[16] In summary, the combination of ultrasound with Doppler studies is the initial study of choice in considering the diagnosis of ovarian torsion; however, it is important for the clinician to appreciate that many of the findings can be subtle and may be negative, particularly in early presentations.

Computed Tomography. When renal colic and appendicitis also are strong considerations in the differential diagnosis for acute pelvic pain, abdominopelvic computed tomography (CT) may be the best initial study, particularly in patients who have a presentation atypical for torsion.[17] In ovarian torsion, CT findings include fallopian tube thickening, smooth wall thickening of the associated adnexal mass, ascites, and uterine deviation to the twisted side[18,19] (Fig. 100-6). Associated hemorrhage in patients with hemorrhagic infarction can be seen. A retrospective review

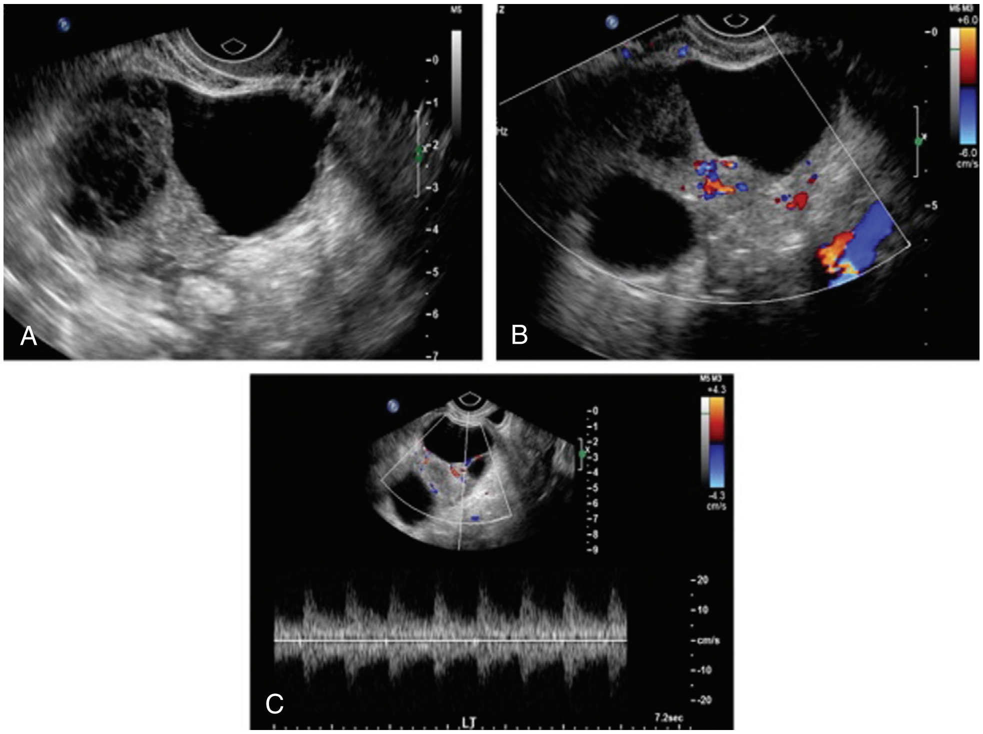

Figure 100-5. Arterial Doppler signal without venous signal in patient with surgically proven torsion. Ultrasound examination also demonstrated an associated hemorrhagic cyst. (From Andreotti RF, Shadinger L, Fleischer A: The sonographic diagnosis of ovarian torsion: Pearls and pitfalls. Ultrasound Clin 2:155, 2007.)

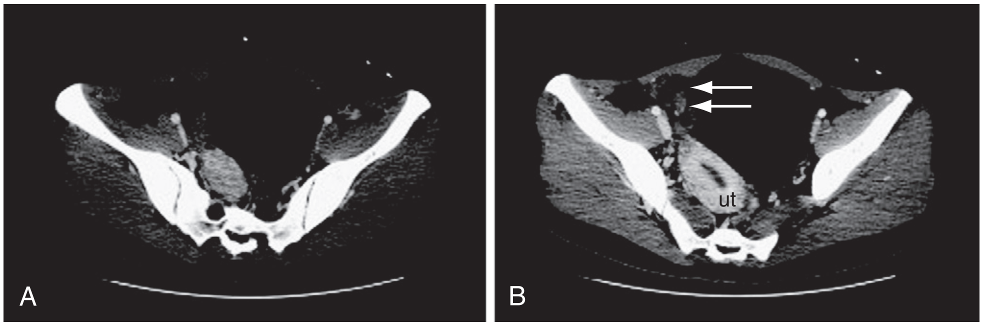

Figure 100-6. Computed tomography scans of the pelvis of a patient with adnexal torsion. Findings include a thickened fallopian tube, associated adnexal mass (arrows in **B**), and deviation of the uterus *(ut)* toward the twisted adnexa. (From Andreotti RF, Shadinger L, Fleischer A: The sonographic diagnosis of ovarian torsion: Pearls and pitfalls. Ultrasound Clin 2:155, 2007.)

of CT scans of patients with confirmed torsion found that every CT scan had evidence of an abnormality, including ovarian enlargement or the presence of a mass or cyst, suggesting that torsion is unlikely if the CT visualized a normal ovary.[20] In contrast, another study of surgically confirmed ovarian torsion cases found that CT correctly diagnosed 5 of 13 cases (38%), as opposed to ultrasonography, which correctly identified 15 of 21 cases (71%).[3] Therefore, negative imaging findings should be interpreted with caution when clinical suspicion is high, but with lower suspicion a normal-appearing ovary on CT scan can be reassuring.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) is not typically ordered in the ED but may also demonstrate findings consistent with torsion. It is particularly helpful if the diagnosis is not clear, such as with intermittent pain over days, or when the history is highly suggestive but the ultrasound is not conclusive.[21] Findings on MRI suggestive of torsion are similar to those on CT.[18] Box 100-1 lists the common imaging findings in ovarian torsion.

Laparoscopy. A diagnostic laparoscopy is the gold standard investigative modality in patients in whom clinical suspicion is high despite negative imaging results. In 100 nonpregnant patients with an acute abdomen, only 29 of the 66 laparoscopically proven cases of ovarian torsion were diagnosed preoperatively. Laparoscopy also allowed diagnosis of other unsuspected conditions, including ovarian cysts, appendicitis, and pelvic inflammatory disease.[22]

Differential Considerations

Considerations in the differential diagnosis include other causes of acute lower abdominal pain, such as appendicitis, ovarian cyst, urinary tract infection, renal calculi, pelvic inflammatory disease, diverticulitis, and ectopic pregnancy. A pregnancy test and pelvic

www.ketabpezeshki.com 66485457-66963820

imaging with either ultrasound or CT if necessary can usually distinguish between these possibilities.

Management

Once the diagnosis of ovarian torsion has been made, the patient should be taken to the operating room as soon as possible. Pediatric patients taken to surgery more than 24 hours later have been found to have a zero salvage rate, compared with patients who had the best chance for salvage—those who were taken to the operating room within 8 hours.[23] The ovary often will recover even if black in appearance at the time of surgery because of its dual blood supply, so attempts at ovarian salvage are warranted even if the diagnosis is made late.[24] This is particularly true in adolescent patients. Ovarian function returns in a majority of patients with surgery that saves the ovary.[23] Additional imaging studies, such as MRI, are an option if the diagnosis is not clear. Because torsion of a normal-appearing ovary is very rare, patients with a normal-appearing ovary on CT or ultrasound scan may be discharged from the ED.

Box 100-1 Imaging Characteristics of Adnexal Torsion

Ultrasonography
Enlargement of the ovary
Associated ovarian mass
Loss of enhancement
Edema
Free pelvic fluid
Loss of venous waveforms
Loss of arterial waveforms

Computed Tomography and Magnetic Resonance Imaging
Enlargement of the ovary
Associated ovarian mass
Thickening of the fallopian tube
Free pelvic fluid
Edema of the ovary
Deviation of the uterus to the affected side
Associated hemorrhage

OVARIAN CYSTS AND MASSES

Principles of Disease

Ovarian cysts are the most common cause of gynecologic masses. They occur at any stage of life but are most frequent in the reproductive years because of the cyclic changes of the ovary associated with menstruation (Fig. 100-7). Most ovarian cysts are benign and resolve with no interventions, but on occasion they may be malignant or associated with significant complications such as hemorrhage or torsion.

The most common type of cyst is a simple, follicular cyst. A follicular cyst develops normally during the first half of the menstrual cycle and is considered pathologic when it is greater than 2.5 cm in diameter. It is thin walled and typically filled with clear fluid. A corpus luteum is considered to be a corpus luteal cyst when it attains a diameter greater than 3 cm. Several other types of cystic masses can occur in the ovary, including other types of cysts, non-neoplastic lesions such as benign cystic teratoma, and various types of ovarian malignancy.

Clinical Features

The most common presentation for patients with an ovarian cyst is pelvic pain. Rupture of a follicular cyst may produce transient pelvic pain or be associated with dyspareunia or may be asymptomatic. Because of its thin, fragile wall, a follicular cyst may rupture during sexual intercourse or during the pelvic examination. Follicular cysts are rarely associated with hemorrhage. Presentation of a corpus luteal cyst may range from an asymptomatic mass to dull, chronic pelvic pain to severe pain associated with rupture. Rupture of a corpus luteal cyst is frequently associated with a significant degree of hemorrhage. As with a follicular cyst, rupture may follow a pelvic examination, sexual intercourse, exercise, or trauma. Rupture of a large or complex cyst may result in severe pain and peritoneal signs, particularly if the associated bleeding is considerable. Occasionally a large cyst may be discov-

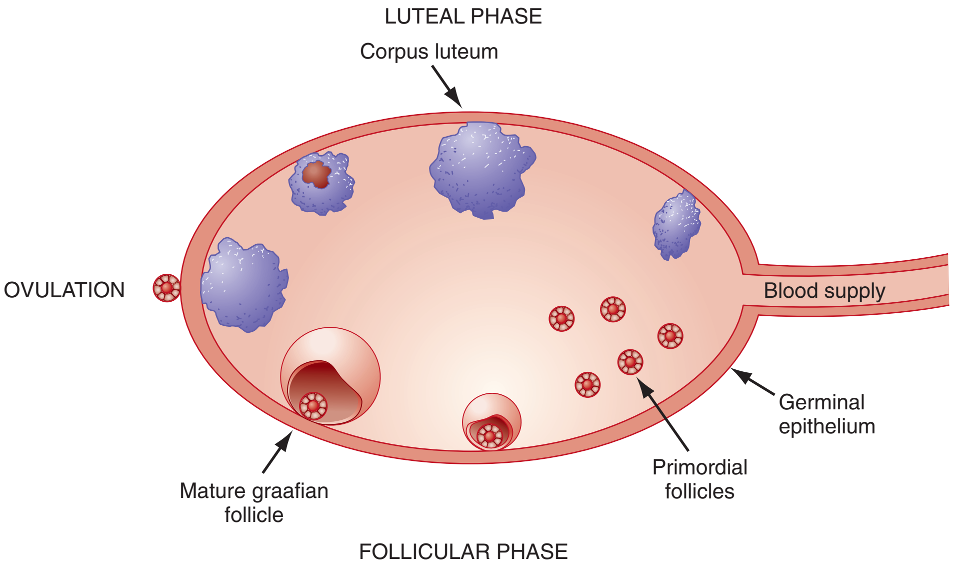

Figure 100-7. Ovarian function during the normal menstrual cycle. (From Lambert MJ, Villa M: Gynecologic ultrasound in emergency medicine. Emerg Med Clin North Am 22:683, 2004.)

www.ketabpezeshki.com 66485457-66963820

ered on a routine pelvic examination as an asymptomatic mass, but this is less common.

Diagnostic Strategies

Laboratory Tests

The initial step in the evaluation of pelvic pain or a pelvic mass is to exclude pregnancy with a urine or serum β-human chorionic gonadotropin (β-hCG) test. A hematocrit may be valuable in the unstable patient as a marker of blood loss.

Imaging

Ultrasonography. Ultrasonography is the standard initial imaging modality used to diagnose and characterize all ovarian pathologic processes and lesions including cysts and masses. Both transabdominal and endovaginal examinations provide useful information. The transabdominal approach permits an overall view of the pelvis and will visualize large masses and pelvic free fluid. Use of the endovaginal probe will provide a detailed picture of the ovary.[10] Figures 100-8 and 100-9 present endovaginal views of a normal ovary, and Figure 100-10 illustrates a simple cyst. Follicular cysts are part of the normal architecture of the ovary, but a cyst is considered to be pathologic if it is larger than 2.5 cm in diameter. Depending on the timing of the scan and the degree of clot formation and lysis, hemorrhage may be seen as well. Ultrasound findings suggestive of malignancy include internal septations, solid elements, internal echoes, daughter cysts, thickened wall, and large amounts of ascites or free fluid.[10]

Computed Tomography. When the differential diagnosis of unilateral pelvic pain is broad, particularly in the patient with associated gastrointestinal symptoms or more diffuse pain, a CT scan may be the initial imaging study. CT scan can also detect a cyst and associated complications including torsion as noted earlier. A follow-up ultrasound examination may be useful in select cases after the CT scan has been obtained, particularly if the cyst is complex. CT findings suggestive of malignancy are cystic-solid mass; necrosis in a solid lesion; cystic lesion with thick, irregular walls, papillary projections, or both; and the presence of ascites, peritoneal metastases, and lymphadenopathy.[25]

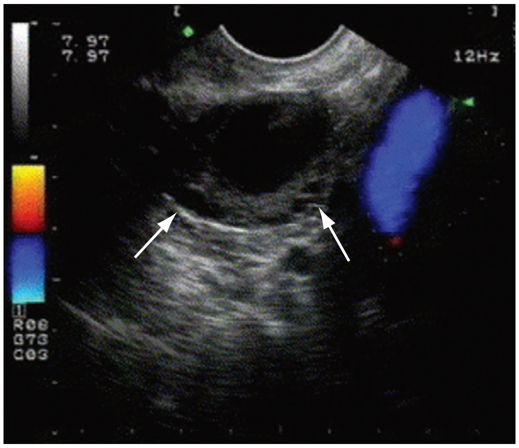

Figure 100-8. Endovaginal ultrasound image of a normal ovary with a dominant follicle *(arrows).* (From Lambert MJ, Villa M: Gynecologic ultrasound in emergency medicine. Emerg Med Clin North Am 22:683, 2004.)

Differential Considerations

It is important to rule out other causes of pelvic pain that require intervention, such as ectopic pregnancy, pelvic inflammatory disease, urinary tract infections, renal colic, appendicitis, and diverticulitis. Cysts range from the benign, simple cyst to ovarian malignancies, so the specific appearance of the cyst is important. Large cysts or masses are a risk factor for ovarian torsion.

Management

Patients with a simple cyst and decrease in their symptoms may be safely discharged with referral for outpatient gynecologic follow-up to ensure resolution of the cyst. Most uncomplicated, simple cysts will resolve within a month. A recent prospective study followed premenopausal patients diagnosed with benign (<6 cm) cysts treated with conservative management for a median of 42 months.[26] Lesions included simple cysts, hemorrhagic cysts, endometriomas, and hydrosalpinx. All the cysts resolved after 2 years, and no patients developed signs and symptoms of ovarian cancer. A complex cyst requires more urgent gynecologic intervention, and these patients may benefit from gynecology consultation in the ED, particularly if reliable follow-up is unlikely or if the patient is particularly symptomatic.

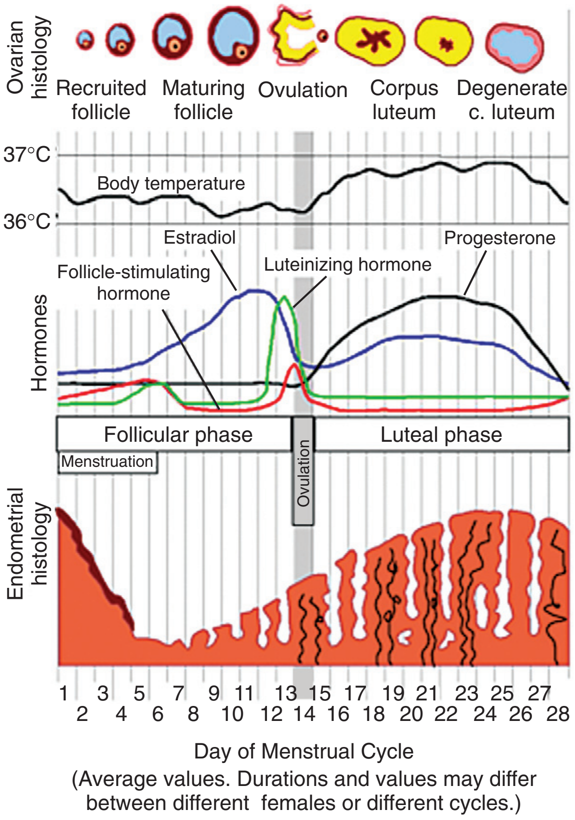

Figure 100-11. Normal menstrual cycle.

ABNORMAL UTERINE BLEEDING IN THE NONPREGNANT PATIENT

Principles of Disease

An understanding of the normal menstrual cycle is invaluable in considering potential causes of abnormal uterine bleeding (Fig. 100-11). The menstrual cycle starts on the first day of menses. During the first part of the menstrual cycle, the endometrium thickens under the influence of estrogen, and a dominant follicle develops in the ovary, releasing an ovum at the midpoint of the cycle. After ovulation, the luteal phase begins and is characterized by production of progesterone from the corpus luteum. Progesterone matures the lining of the uterus, and if implantation does not occur, the corpus luteum dies, accompanied by sharp drops in progesterone and estrogen. These changes typically are followed by menstruation. Menstrual bleeding is usually predictable and cyclic and results from withdrawal of the effects of hormones on the endometrium, which occurs approximately 14 days after ovulation.

Disruption of the hypothalamic-pituitary-ovarian axis from a variety of causes can result in abnormal uterine bleeding. Returning the balance of estrogen and progesterone with oral contraceptives will help many patients regulate the cycle, with reduction in or cessation of abnormal uterine bleeding.[26-30]

Clinical Features

History

Abnormal uterine bleeding is a common presentation in the ED. A large number of possible conditions can cause abnormal uterine bleeding, and a systematic history and physical examination can help narrow the possibilities. Table 100-1 lists terms frequently used to describe abnormal uterine bleeding. (See Chapter 34 for further discussion.)

Table 100-1 Abnormal Uterine Bleeding

TERM	BLEEDING PATTERN
Menorrhagia	Bleeding occurring at regular intervals but with heavy flow (≥80 mL) or duration (≥7 days)
Intermenstrual bleeding	Irregular bleeding between cycles
Amenorrhea	Bleeding absent for 6 mo or more in a nonmenopausal woman
Midcycle spotting	Spotting occurring just before ovulation, typically from declining estrogen levels
Postmenopausal bleeding	Recurrence of bleeding in a menopausal woman at least 1 year after cessation of cycles
Acute emergent abnormal uterine bleeding	Bleeding characterized by significant blood loss that results in hypovolemic shock
Dysfunctional uterine bleeding	Ovulatory or anovulatory bleeding, diagnosed after the exclusion of pregnancy, medications, iatrogenic causes, genital tract pathology, and systemic disease

Vaginal bleeding before the age of menarche is abnormal and is often the result of trauma, such as sexual abuse, or a structural lesion.[31] In a woman of reproductive age, abnormal uterine bleeding includes a change in the duration, frequency, or amount of bleeding, or bleeding between menstrual cycles. In the postmenopausal woman, any bleeding 12 months after the cessation of menses or unpredictable bleeding during hormone therapy should be considered abnormal. The amount and frequency of bleeding and the duration of symptoms, as well as the relationship to the menstrual cycle, should be established.[32] A menstrual cycle that is fewer than 21 days in duration or more than 35 days long or flow for less than 2 days or more than 7 days is classified as abnormal. A pattern of irregular bleeding between cycles or an abrupt change in the previous pattern of bleeding should be determined.[33] Systemic disease, such as liver disease, diabetes, or thyroid disease, may be associated with abnormal uterine bleeding.[34] Endometrial cancer is associated with underlying diabetes mellitus, anovulatory cycles, obesity, nulliparity, and age older than 35 years.[29] Cervical dysplasia or other genital tract pathology may cause postcoital or irregular bleeding.[35] Disruption along the hypothalamus-pituitary-ovarian pathway frequently is the cause of abnormal uterine bleeding. Causes of hypothalamic suppression include excessive exercise, stress, and weight loss.[36] Polycystic ovary syndrome (PCOS) results in excess estrogen production.

According to Dilley and colleagues, 10.7% of patients with heavy menstrual bleeding have an underlying coagulation disorder, most commonly von Willebrand's disease.[37] Although most patients with abnormal uterine bleeding do not require evaluation for coagulopathy, the diagnosis is suggested by a family history of a bleeding disorder, prolonged history of heavy menses, excessive bleeding with surgery or dental procedures, or easy bruising.[38] Box 100-2 lists historical factors that suggest a potential cause for the bleeding.[29] Dysfunctional uterine bleeding is a diagnosis of exclusion in a woman of childbearing age after pregnancy, malignancy, and systemic disease have been ruled out.[29] Dysfunctional uterine bleeding typically is classified as anovulatory or ovulatory. Anovulatory bleeding is much more common, resulting from a disturbance of the normal hypothalamic-pituitary-ovarian axis, and is particularly common at the extremes of the reproductive years.[28]

Box 100-2 Differential Diagnosis for Abnormal Uterine Bleeding

- Pregnancy and pregnancy-related conditions
  - Miscarriage
  - Ectopic pregnancy
  - Placenta previa
  - Placental abruption
  - Trophoblastic disease
- Medications and iatrogenic causes
  - Anticoagulants
  - Oral contraceptives
  - Steroids
  - Antipsychotics
  - Intrauterine devices
  - Thyroid hormone replacement
- Systemic disease
  - Cushing's disease
  - Coagulopathies
  - Liver or renal disease
  - Hypothalamic suppression (excessive exercise, weight loss)
  - Polycystic ovary syndrome
  - Thyroid disease
- Genital tract pathology
  - Cervicitis
  - Endometritis
  - Fibroids (leiomyomata)
  - Adenomyosis
  - Malignancy
  - Trauma
  - Foreign body
- Dysfunctional uterine bleeding

Physical Examination

With prolonged, heavy bleeding, signs of chronic anemia may be noted on the physical examination. PCOS is a common cause of abnormal uterine bleeding. Physical findings suggestive of PCOS include obesity, acne, hirsutism, and acanthosis nigricans, which is hyperpigmentation typically seen in the folds of skin in the neck, groin, or axilla.[39] Other causes of bleeding include vaginal or cervical lesions, which may be visible on the speculum examination. A leiomyoma or fibroid uterus may be palpable on the bimanual examination.[40] Patients with endometrial cancer frequently have an enlarged uterus as well.

Diagnostic Strategies

Laboratory Studies

In evaluating a woman of reproductive age with vaginal bleeding, a urine pregnancy test is the most essential laboratory test. In a patient with excessive bleeding, any hemodynamic instability, or clinical evidence of anemia (e.g., excessive fatigue, pale conjunctiva), a hemoglobin or hematocrit may be helpful. Coagulation studies should be considered in patients with underlying liver disease or other coagulopathies.[38]

Imaging

Ultrasonography. Transvaginal ultrasonography may reveal a fibroid uterus, endometrial thickening, or a focal mass.[41] Endometrium measuring less than 4 mm thick is under the influence of low estrogen—for example, either in the early follicular phase or in menopause. Thickened endometrium may indicate an underlying lesion or excess estrogen[42] (Fig. 100-12). For a majority of nonpregnant patients with abnormal uterine bleeding, these ultrasound findings do not immediately affect ED decision-making. In

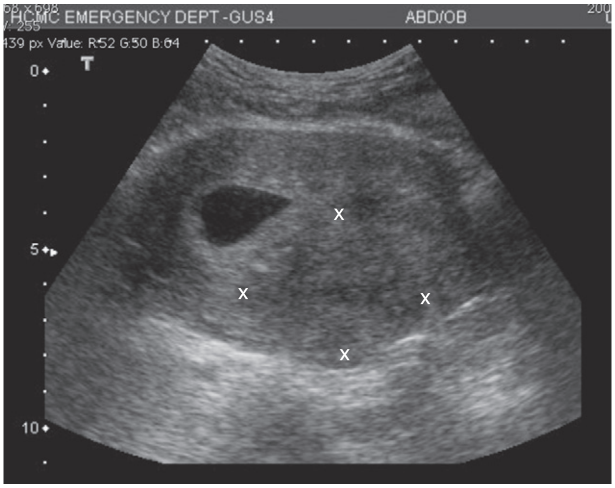

Figure 100-12. Longitudinal view of the uterus with thickened endometrium. (Courtesy Robert Reardon, MD, Hennepin County Medical Center, Minneapolis, Minn.; used with permission.)

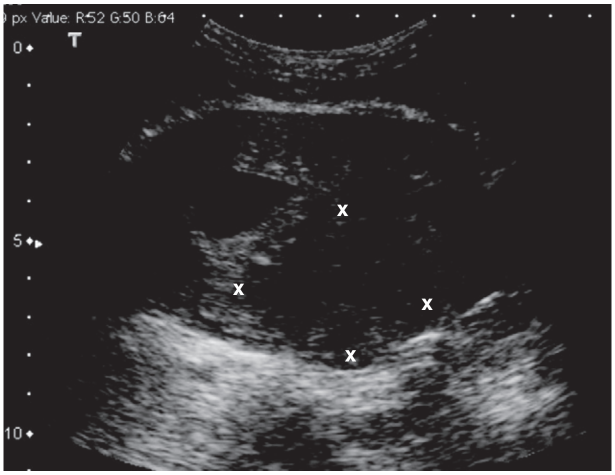

Figure 100-13. Ultrasound image of a uterine fibroid (within Xs). (Courtesy Robert Reardon, MD, Hennepin County Medical Center, Minneapolis, Minn.; used with permission.)

patients who have access to adequate gynecologic services, imaging may be deferred until follow-up evaluation with the gynecologist. The decision to perform ultrasound imaging in the ED will depend on the urgency to determine the cause of bleeding and on the reliability of outpatient follow-up. ED pelvic ultrasound imaging in nonpregnant patients can determine the cause of the bleeding in approximately 60% of cases. Uterine fibroids are by far the most common diagnosis (Fig. 100-13), but in one study 9.6% of patients had endometrial changes suggestive of malignancy,[43] illustrating the importance of arranging follow-up for any patient with new abnormal uterine bleeding.

Differential Considerations

The etiology of abnormal uterine bleeding is extensive and includes systemic disease, structural lesions, such as a fibroid uterus, hormonal abnormalities, and iatrogenic causes, such as medication side effects. A careful physical examination will exclude vaginal or rectal sources of bleeding.

Management

The likely causative disorder, as well as the amount of bleeding, will guide the ED management. Nonsteroidal anti-inflammatory

www.ketabpezeshki.com 66485457-66963820

medications are generally effective for relief of associated cramping pelvic pain.[29] For anovulatory bleeding, combination oral contraceptive pills can help regulate the cycle and also counteract the effects of long-term effects of unopposed estrogen on the endometrium. In a patient who desires contraception and is not heavily bleeding on presentation to the ED, a combination oral contraceptive with 20 to 35 μg of ethinyl estradiol may be prescribed.[28] In the patient with heavy bleeding, an oral contraceptive with 35 μg of estrogen can be taken twice a day for 5 to 7 days until the bleeding stops, at which time the dose is decreased to once a day until the pack is completed.[29] This is often done by prescribing two packs of oral contraceptives and having the patient take one pill from each package until the bleeding stops then continue with one pill daily. Rarely, a patient will have uncontrolled bleeding and signs of significant blood loss on presentation. These patients should receive aggressive resuscitation with saline and blood as with other types of hemorrhagic shock. In these patients, surgical removal of the culprit lesion, if one is present, or an urgent dilation and curettage (D&C) procedure is likely necessary. Alternatively, intravenous conjugated estrogen (Premarin) may be used. The dose is 25 mg intravenously (IV) every 4 to 6 hours until the bleeding stops.[44]

EMERGENCY CONTRACEPTION

Emergency contraception, also commonly known as the *morning-after pill*, consists of therapy to prevent pregnancy after unprotected sexual intercourse. It is estimated that more than 1 million unintended pregnancies could be avoided per year if emergency contraception were used.[45] The most common reasons cited by patients seeking emergency contraception include failure to use contraception and failure of the contraception method, such as a broken condom or missed oral contraceptive pill. A recent survey of 800 women of reproductive age found that only 6% of the women had ever used emergency contraception.[46] Many women are not aware of the availability of this option, are not informed about its safety or use, or do not have access to the medications.[46,47]

Emergency contraception with high-dose estrogen was reported in the early 1960s and began to have widespread use after Yuzpe demonstrated the efficacy of a lower-dose combination of estrogen and progestin to prevent pregnancy in 1974.[45,48,49] At present, levonorgestrel alone, marketed as Plan B in the United States, is more effective and has largely replaced the Yuzpe method.[50] Nausea occurs in 18% of patients using Plan B and in 43% of women taking combination pills.[51] Antiemetics given 1 hour before the combination pills are effective and should be considered with use of these pills. The incidence of nausea is much lower with Plan B, but antiemetics can be offered. The package insert of Plan B recommends taking the 0.75-mg pill as soon as possible and the subsequent dose 12 hours later; however, taking the doses simultaneously is equally effective. Emergency contraception should be administered before 24 hours if possible but can be given up to 120 hours after intercourse. The Yuzpe method is 87 to 90% effective if the regimen is given within 72 hours; this rate drops to 72 to 87% if the pills are given between 72 and 120 hours. Plan B is noted to be 89% effective in preventing pregnancy.[45]

Emergency contraception may be offered after inadequately protected intercourse to any woman who does not desire pregnancy. The typical contraindications to oral contraceptives do not apply to emergency contraception because the duration of therapy is so brief.[52] Emergency contraception has no adverse effects on a developing fetus and does not pose a risk to an established pregnancy.[53] A majority of nonpregnant women experience menses within a week of the expected time, but irregular bleeding may occur.[37] It is still possible for a patient who uses emergency contraception to get pregnant in the same menstrual cycle, so she should be advised to use an alternative form of contraception and to undergo a pregnancy test if menstruation is delayed more than 3 weeks. Advance provision of emergency contraception does not increase the number of unprotected sexual encounters.[54-57]

In 2007, after FDA approval, Plan B became available nationally over the counter without a prescription. Pregnancy rates as well as rates of sexually transmitted diseases and sexual activity have remained unchanged even though the use of emergency contraception has increased.[58] Even though Plan B is available over the counter, follow-up studies highlight ongoing barriers to access, including cost and patient awareness, and highlight the importance of continued education including education on the use of primary contraceptive methods.[59-61]

DISPOSITION

A majority of patients with pelvic pain from ovarian cysts or abnormal uterine bleeding without hemodynamic compromise may be managed with specific therapies to minimize symptoms and should be referred to a gynecologist for definitive management on an outpatient basis. Patients with confirmed or suspected ovarian torsion or severe, acute abnormal uterine bleeding and hemodynamic instability require urgent gynecology consultation and hospitalization. Patients who receive emergency contraception should be counseled regarding birth control and have a follow-up pregnancy test should they miss their next period.

KEY POINTS

- Ovarian torsion is easily missed on initial presentation. This diagnosis should be a consideration in any patient with known risk factors, even if symptoms are subtle or atypical.
- Abnormal uterine bleeding has many structural and hormonal causes. A careful history and physical examination and selected imaging can often allow determination of the likely cause.
- Ultrasound examination may distinguish among the various types of ovarian cysts and identify associated complications such as torsion and hemorrhage.
- Emergency contraception is a safe, effective option to prevent undesired pregnancy. Levonorgestrel (progestin) as Plan B is more effective and is associated with fewer side effects than the traditional Yuzpe method.

Chapter 101

Stroke

Todd J. Crocco and Joshua N. Goldstein

PERSPECTIVE

Background

Stroke is the third leading cause of death in the United States and a leading cause of long-term disability.[1] It affects about 795,000 people per year. On average, someone has a stroke every 40 seconds, and someone dies of a stroke every 4 minutes.[2] Stroke patients have an in-hospital mortality rate of 5 to 10% for ischemic stroke and 40 to 60% for intracerebral hemorrhage (ICH).[3] Only 10% of stroke survivors will recover completely. The remaining survivors will be left with an impairment that will often necessitate rehabilitation.[4] The estimated direct and indirect cost of stroke in the United States in 2010 was $73.7 billion.[2]

Stroke can be defined as any vascular injury that reduces cerebral blood flow (CBF) to a specific region of the brain, causing neurologic impairment. The onset of symptoms may be sudden or stuttering, often with transient or permanent loss of neurologic function. Approximately 87% of all strokes are ischemic in origin, caused by the occlusion of a cerebral vessel.[2] Approximately 13% are hemorrhagic strokes caused by the rupture of a blood vessel into the parenchyma of the brain (ICH) or into the subarachnoid space (subarachnoid hemorrhage [SAH]).[2] Only ischemic stroke and ICH are discussed in this chapter.

Before the development of interventional strategies, treatment for stroke consisted of stabilization, observation, and rehabilitation. More recently, a better understanding of the pathophysiology of neuronal injury and the introduction of new therapies have led to a shift from observation to early evaluation and treatment. Current interventional treatment regimens include blood pressure (BP) management, anticoagulation, thrombolytic therapy, catheter-based interventions, and surgery. The key to success is early identification and treatment of patients with stroke before neurologic deficits become irreversible.

Epidemiology

Ischemic Stroke

An estimated 610,000 "first-ever" ischemic strokes occur each year in the United States.[2] These may result either from in situ thrombosis or embolic obstruction from a more proximal source, usually the heart. In more than one third of these first-ever strokes, no clear cause is identified[5-7] (Table 101-1).

Approximately one third of all ischemic strokes are thrombotic in nature. These can be caused by either large- or small-vessel occlusions. Common areas for large-vessel occlusions are cerebral vessel branch points, especially in the distribution of the internal carotid artery. Thrombosis usually results from clot formation in the area of an ulcerated atherosclerotic plaque that forms in the area of turbulent blood flow, such as a vessel bifurcation. A marked reduction in flow results when the stenosis occludes more than 90% of the blood vessel diameter. With further ulceration and thrombosis, platelets adhere to the region. A clot then either embolizes or occludes the artery.

Lacunae, or small-vessel strokes, involve small terminal sections of the vasculature and more commonly occur in African Americans and patients with diabetes and hypertension.[5] A history of hypertension is present in 80 to 90% of patients who experience lacunar strokes. The subcortical areas of the cerebrum and brainstem often are involved. The infarcts range in size from a few millimeters to 2 cm and are seen most commonly in the basal ganglia, thalamus, pons, and internal capsule. They may be caused by small emboli or by a process termed *lipohyalinosis*, which occurs in patients with hypertensive cerebral vasculopathy. Although nearly 20 lacunar syndromes have been described, the most common of these lacunar syndromes are pure motor strokes, pure sensory strokes, or ataxic hemiparesis. Because they are subcortical and well localized, lacunar strokes do not typically cause cognitive impairment, aphasia, or simultaneous sensorimotor findings.

One fourth of all ischemic strokes are cardioembolic in nature.[5,6] Embolization of a mural thrombus in patients with atrial fibrillation is the most common mechanism, and patients with atrial fibrillation have an approximate fivefold increased risk for development of a stroke.[8] In addition, roughly 45% of all embolic strokes occur as a result of atrial fibrillation.[8] Noncardiac sources of emboli may include diseased portions of extracranial arteries, resulting in an artery-to-artery embolus. One common example is amaurosis fugax, in which emboli from a proximal carotid artery plaque embolizes to the ophthalmic artery, causing transient monocular blindness.

Another cause of stroke is recent myocardial infarction (MI). Approximately 12 ischemic strokes occur per 1000 nonfatal MI patients within 1 month after the index event. Furthermore, 11 ischemic strokes occur per 1000 nonfatal MI patients in the post-MI hospitalization period. Independent predictors of stroke after acute MI are advanced age, diabetes, hypertension, history of previous stroke, anterior location of index MI, previous MI, atrial fibrillation, heart failure, and nonwhite race.[9] The use of aspirin has been shown to reduce the incidence of post-MI stroke by 46%.[10]

Approximately 3 to 4% of all strokes occur in patients aged 15 to 45 years. Although atherosclerosis is the most common cause in older patients, causative disorders and conditions in younger patients often are uncommon and may be reversible. Pregnancy, the use of oral contraceptives, antiphospholipid antibodies (such as lupus anticoagulant and anticardiolipin antibodies), protein S and C deficiencies, sickle cell anemia, and polycythemia all

Table 101-1 Estimated Number per Year of First-Ever Strokes and Transient Ischemic Attacks (TIAs) in the United States

STROKE SUBTYPE	ESTIMATED NUMBER
Large vessel	69,000 (16%)
Small vessel/lacunae	76,000 (17.5%)
Cardioembolic	113,000 (26%)
Stroke of uncommon mechanisms	15,000 (3.5%)
Infarction of unknown cause	157,000 (36.5%)
Total strokes and TIAs	430,000 (100%)

Data from Woo D, et al: Incidence rates of first-ever ischemic stroke subtypes among blacks: A population-based study. Stroke 30:2517, 1999; and Petty GW, et al: Ischemic stroke subtypes: A population-based study of incidence and risk factors. Stroke 30:2513, 1999.

predispose patients to sludging or thrombosis, thereby increasing the risk of stroke. Fibromuscular dysplasia of the cerebral vasculature also may lead to stroke, and in rare instances prolonged vasoconstriction from a migraine syndrome causes stroke. Recreational drugs such as cocaine, phenylpropanolamine, and amphetamines are potent vasoconstrictors that have been associated with both ischemic and hemorrhagic stroke.

Carotid and vertebral dissections often are associated with trauma but may follow such mild events as turning the head sharply. Carotid and vertebral dissections also are seen more frequently in people with underlying pathology of the vessel wall, such as in fibromuscular dysplasia and connective tissue disorders. Alteration in the vessel intima can lead to vessel stenosis, occlusion, or embolism. The patient may report a minor preceding event such as spinal manipulation, yoga, working overhead, coughing, or vomiting. Presenting manifestations may include headache, facial pain, visual changes, cranial nerve (CN) palsies, pain over the affected vessel, Horner's syndrome, amaurosis fugax, SAH, or an ischemic stroke. The headache frequently is unilateral and may occur days before onset of the other neurologic symptoms.[11] Although angiography has been the standard diagnostic study, dissections are increasingly being diagnosed by less invasive modalities such as ultrasonography, magnetic resonance angiography (MRA), and computed tomography angiography (CTA).[12] Medical therapy includes early anticoagulation if SAH is not suspected. If symptoms recur despite anticoagulation, the patient may be eligible for endovascular intervention. Carotid or vertebral dissection is not considered a contraindication to use of tissue plasminogen activator (tPA) in the eligible patient.[13] This entity is considered a major cause of stroke in younger patients.[11,14,15]

A *transient ischemic attack* (TIA) was historically defined as a neurologic deficit with complete resolution within 24 hours. However, advances in neuroimaging suggest that many such events represent minor stroke with resolved symptoms rather than true TIAs.[16] Therefore the American Heart Association (AHA) recommends the following definition: a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction.[17]

From 200,000 to 500,000 TIAs per year are diagnosed in the United States, and emergency department (ED) visits for TIA occur at a rate of about 1 visit per 1000 population.[16] TIAs constitute an important warning sign for the future development of cerebral infarction. Approximately 10% of the patients who experience a TIA will experience a stroke within 3 months of the sentinel event, and one half of these occur within the first 2 days.[18]

Box 101-1 Most Common Sites for Hypertensive Intracranial Hemorrhage

Affected Area	Frequency
Putamen	44%
Thalamus	13%
Cerebellum	9%
Pons	9%
Other cortical areas	25%

Hemorrhagic Stroke

Spontaneous ICH causes 10 to 15% of all acute strokes, affecting approximately 65,000 patients per year.[19] It carries a 30-day mortality rate of up to 50%, with one half of patients dying in the first 2 days. Among survivors, only 1 in 5 are living independently at 6 months.[3]

The two major underlying causes of ICH are hypertensive vasculopathy (caused by long-standing hypertension) and cerebral amyloid angiopathy (usually found in elders, the result of amyloid deposition in cerebral vessel walls). Hypertensive hemorrhage results from degenerative changes in the small penetrating arteries and arterioles, leading to lipohyalinosis of small, deep penetrating arteries. Such hemorrhages generally occur in the deep regions including basal ganglia and thalamus. The most common sites for hypertensive hemorrhage are listed in Box 101-1. ICH caused by amyloid angiopathy tends to be lobar in nature and to occur more commonly in elders. Specific apolipoprotein E alleles appear to predispose to the development and recurrence of ICH.

Other factors leading to ICH include underlying vascular malformations, including arteriovenous malformations (AVMs) and aneurysms, drug intoxication (particularly sympathomimetics, such as cocaine), malignant hypertension, saccular aneurysms, blood dyscrasias, venous sinus thrombosis, hemorrhagic transformation of an ischemic stroke, moyamoya disease, and tumors. High-risk features for such secondary forms of ICH include lobar location, presence of intraventricular blood, and younger age.[20]

PRINCIPLES OF DISEASE

Pathophysiology

The cerebral vasculature supplies the brain with a rich flow of blood that contains the critical supply of oxygen and glucose necessary for normal brain function. When a stroke occurs, there are immediate alterations in CBF and extensive changes in cellular homeostasis. The normal CBF is approximately 40 to 60 mL/100 g of brain per minute. When CBF drops below 15 to 18 mL/100 g of brain per minute, several physiologic changes occur. The brain loses electrical activity, becoming electrically "silent," although neuronal membrane integrity and function remain intact. Clinically, the areas of the brain maintaining electrical silence manifest a neurologic deficit, even though the brain cells are viable. When CBF is below 10 mL/100 g of brain per minute, membrane failure occurs, with a subsequent increase in the extracellular potassium and intracellular calcium and eventual cell death. The ischemic penumbra is the area of the brain surrounding the primary injury, which is preserved by a tenuous supply of blood from collateral vessels. This border zone of neuronal tissue is the area of greatest interest to investigators for possible salvage in both ischemic and hemorrhagic stroke. In ischemic stroke, the duration of occlusion plays a critical role in neuronal survival.[21] Increasing the duration of occlusion increases both the irreversibility of deficits and the amount of cerebral infarction. Thus, ischemic stroke trials typically focus on the first few hours after symptom onset.

www.ketabpezeshki.com 66485457-66963820

In ICH, acute vessel rupture is most often caused by underlying small vessel disease, as noted earlier, and causes injury by several mechanisms. First, there is mass effect from the hematoma itself, followed by activation of the coagulation cascade, release of inflammatory cytokines, and blood-brain barrier (BBB) disruption. This leads to perihematomal edema formation and secondary brain injury. Finally, continued bleeding, or hematoma expansion, occurs in many patients—either continued bleeding from the primary source or secondary bleeding at the periphery of the hemorrhage.[19]

Anatomy and Physiology

Blood is supplied to the brain by the anterior and posterior circulations. The anterior circulation originates from the carotid system and perfuses 80% of the brain including the optic nerve, retina, and frontoparietal and anterior-temporal lobes. The first branch off the internal carotid artery is the ophthalmic artery, which supplies the optic nerve and retina. As a result, the sudden onset of painless monocular blindness (amaurosis fugax) identifies the stroke as involving the anterior circulation (specifically the ipsilateral carotid artery) at or below the level of the ophthalmic artery. The internal carotid arteries terminate by branching into the anterior and middle cerebral arteries at the circle of Willis.

The anterior cerebral artery supplies the basal and medial aspects of the cerebral hemispheres and extends to the anterior two thirds of the parietal lobe. The middle cerebral artery feeds the lenticulostriate branches that supply the putamen, part of the anterior limb of the internal capsule, the lentiform nucleus, and the external capsule. Main cortical branches of the middle cerebral artery supply the lateral surfaces of the cerebral cortex from the anterior portion of the frontal lobe to the posterolateral occipital lobe.

Although the posterior circulation is smaller and supplies only 20% of the brain, it supplies the brainstem (which is critical for normal consciousness, movement, and sensation), cerebellum, thalamus, auditory and vestibular centers of the ear, medial temporal lobe, and visual occipital cortex. The posterior circulation is derived from the two vertebral arteries that ascend through the transverse processes of the cervical vertebrae. The vertebral arteries enter the cranium through the foramen magnum and supply the cerebellum by the posterior inferior cerebellar arteries. They join to form the basilar artery, which branches to form the posterior cerebral arteries.

The extent of injury in either an anterior or a posterior stroke depends on both the vessel involved and the presence of collateral blood flow distal to the vessel occlusion. A patient with excellent collateral blood flow from the contralateral hemisphere may have minimal clinical deficits despite a complete carotid occlusion. By contrast, a patient with poor collateral flow may have hemiplegia with the same lesion.

CLINICAL FEATURES

Ischemic Stroke

The signs and symptoms of an ischemic stroke may appear suddenly and without warning or may have a stuttering, insidious onset. Disruption of the flow to one of the major vascular limbs of the cerebral circulation will result in physiologic disruption to the anatomic area of the brain supplied by that blood vessel. Ischemic strokes can be classified as anterior or posterior circulation strokes depending on the vasculature involved. The presence of neurologic deficits is highly dependent on collateral flow. In addition to the vascular supply involved, ischemic strokes can be further described by the temporal presentation of their neurologic deficits. A "stroke in evolution" is one in which focal neurologic deficits worsen over the course of minutes or hours. Approximately 20% of anterior circulation strokes and 40% of posterior circulation strokes will show evidence of progression. Anterior circulation strokes may progress within the first 24 hours, whereas posterior strokes may progress for up to 3 days. Propagation of thrombus is postulated as a likely mechanism for progression. With anterior circulation strokes (involving variously and primarily the carotid, anterior, and middle cerebral arteries), the clinical presentation rarely includes complete loss of consciousness unless the lesion occurs in the previously unaffected hemisphere of a patient who has experienced a previous contralateral stroke. Occlusions in the anterior cerebral artery mainly affect frontal lobe function. The patient has altered mentation coupled with impaired judgment and insight, as well as the presence of primitive grasp and suck reflexes on physical examination. Bowel and bladder incontinence may be features of anterior cerebral artery stroke. Paralysis and hypesthesia of the lower limb opposite the side of the lesion are characteristic. Leg weakness is more pronounced than arm weakness in anterior cerebral distribution stroke. Apraxia or clumsiness in the patient's gait also may be noted.

Marked motor and sensory disturbances are the hallmarks of occlusion of the middle cerebral artery. They occur on the side of the body contralateral to the side of the lesion and usually are worse in the arm and face than the leg. Such disturbances may involve only part of an extremity or the face but almost always are accompanied by numbness in the same region as that of the motor loss. Hemianopsia, or blindness in one half of the visual field, occurs ipsilateral to the lesion. Agnosia, or the inability to recognize previously known subjects, is common, and aphasia may be present if the lesion occurs in the dominant hemisphere. Patients often have a gaze preference toward the affected hemisphere because of disruption of the cortical lateral gaze centers. The clinical aphorism is that a patient looks *at* a destructive lesion (stroke) but *away from* an irritative lesion (seizure focus).

Aphasia, a disorder of language in which the patient articulates clearly but uses language inappropriately or understands it poorly, also is common in dominant-hemisphere stroke. Aphasia may be expressive, receptive, or a combination of both. *Wernicke's aphasia* occurs when the patient is unable to process sensory input such as speech and thus fails to understand verbal communication (receptive aphasia). *Broca's aphasia* refers to the inability to communicate verbally in an effective way, even though understanding may be intact (expressive aphasia). Aphasia should be distinguished from dysarthria, which is a motor deficit of the mouth and speech muscles; the dysarthric patient articulates poorly but understands words and word choices. Aphasia is important to recognize because it usually localizes a lesion to the dominant (usually left) cerebral cortex in the middle cerebral artery distribution. *Aphasia* and *dysphasia* are terms that are used interchangeably but must be distinguished from *dysphagia,* which is difficulty in swallowing.

Pathology in the vertebrobasilar system (i.e., posterior circulation strokes) can cause the widest variety of symptoms and as a result may be the most difficult to diagnose. The symptoms reflect CN deficits, cerebellar involvement, and involvement of neurosensory tracts. The brainstem also contains the reticular activating system, which is responsible for mediating consciousness, and the emesis centers. Unlike those with anterior circulation strokes, patients with posterior circulation stroke can have loss of consciousness and frequently have nausea and vomiting. The posterior cerebral artery supplies portions of the parietal and occipital lobes, so vision and thought processing are impaired. Visual agnosia, the inability to recognize seen objects, may be a feature, as may alexia, the inability to understand the written word. A third nerve palsy may occur, and the patient may experience homonymous hemianopsia. One of the more curious facets of this

www.ketabpezeshki.com 66485457-66963820

syndrome is that the patient may be unaware of any visual problem (visual neglect). Vertigo, syncope, diplopia, visual field defects, weakness, paralysis, dysarthria, dysphagia, spasticity, ataxia, or nystagmus may be associated with vertebrobasilar artery insufficiency. Posterior circulation strokes also demonstrate crossed deficits, such as motor deficits on one side of the body and sensory loss on the other. In anterior circulation strokes, by contrast, abnormalities are always limited to one side of the body.

A focused neurologic examination should assess level of consciousness, speech, CN function, motor and sensory function, and cerebellar function. Level of consciousness and fluency of speech can be rapidly assessed in a dialogue with the patient to determine the presence of dysarthria or aphasia. The head should be evaluated for signs of trauma. Pupillary size and reactivity and extraocular movements provide important information about brainstem function, particularly CN III through CN VI; an abnormal third nerve function may be the first sign of tentorial herniation. Gaze preference suggests brainstem or cortical involvement. Central facial nerve weakness from a stroke should be distinguished from the peripheral causes of CN VII weakness. With a peripheral lesion, the patient is unable to wrinkle the forehead. Assessment of facial sensation, eyebrow elevation and squinting, smiling symmetry, gross auditory acuity, gag reflex, shoulder elevation, sternocleidomastoid strength, and tongue protrusion complete the CN evaluation.

Motor and sensory testing is performed next. Muscle tone can be assessed by moving a relaxed limb. Proximal and distal muscle group strength is assessed against resistance. Pronator drift of the arm is a sensitive sign of motor weakness and can be tested simultaneously by having the patient sit with eyes closed and arms outstretched, with palms toward the ceiling, for 10 seconds. Asymmetrical sensation to pain and light touch may be subtle and difficult to detect. Double simultaneous extinction evaluation tests for sensory neglect and can be easily performed by simultaneously touching the right and left limbs. The patient may feel both the right and left sides being touched individually but may not discern touch on one side when both are touched simultaneously. Similarly, the ability to discern a number gently scratched on a forearm, graphesthesia, is another easily tested cortical parietal lobe function. These tests can help differentiate a pure motor deficit of a lacunar stroke from a sensorimotor middle cerebral artery deficit.

Cerebellar testing and the assessment of reflexes and gait complete the examination. Finger-to-nose and heel-to-shin evaluations are important tests of cerebellar functions. Asymmetry of the deep tendon reflexes or unilateral Babinski's sign may be an early finding of corticospinal tract dysfunction. Gait testing is commonly omitted yet is one of the most informative parts of the neurologic examination. Observing routine ambulation and heel-to-toe walking can assess for subtle ataxia, weakness, or focal cerebellar lesions.

The National Institutes of Health Stroke Scale (NIHSS) is a useful and rapid tool for quantifying neurologic deficit in patients with stroke and can be used in determining treatment options[22] (Box 101-2). NIHSS scores have been shown to be reproducible and valid and to correlate well with the amount of infarcted tissue on CT scan.[23,24] The baseline NIHSS score can identify patients who are appropriate candidates for fibrinolytic therapy as well as those at increased risk for hemorrhage. In addition, it has been used as a prognostic tool to predict outcome and is currently being used by some stroke centers to stratify patients for entry into treatment trials.[22]

Hemorrhagic Stroke

The classic presentation of ICH is the sudden onset of headache, vomiting, severely elevated BP, and focal neurologic deficits that progress over minutes. Similar to ischemic stroke, ICH is often associated with a motor and sensory deficit contralateral to the brain lesion. Almost 40% of patients will demonstrate significant growth in hemorrhage volume within the first few hours.[25]

Although headache, vomiting, and coma are common, many patients do not have these findings, and the clinical presentation can be identical to that of patients with ischemic stroke; the two cannot reliably be differentiated in the absence of neuroimaging (Table 101-2).

Ongoing assessment of airway and mental status is of paramount importance in patients with ICH because precipitous deterioration is always a possibility. Emergency airway management requires careful judgment. On the one hand, airway control can prevent aspiration, hypoxia, and hypercarbia; on the other, sedation and paralysis can make it difficult to follow the neurologic examination, which can help monitor for hemorrhage expansion, elevated intracranial pressure (ICP), seizure activity, and brainstem herniation.

As with ischemic stroke, a careful neurologic examination is important in localizing the region and extent of injury. Baseline NIHSS and Glasgow Coma Scale (GCS) scores can be used to assess stroke severity, although the GCS score may be more feasible to follow for neurologic deterioration (Box 101-3). In addition, serial examinations can detect early changes that may suggest ongoing bleeding during the acute phase.

Poor prognostic indicators for patients with ICH include a decreased level of consciousness on arrival, intraventricular hemorrhage, and large ICH volume, all of which can be assessed in the ED. The ABC/2 technique is a quick and accurate method of measuring ICH volume at the bedside[26] (Fig. 101-1). One validated tool to predict outcome is the ICH score (Box 101-4)[21]: Patients are given 0 to 2 points for GCS score, 1 point for age over 80, 0 to 2 points for ICH volume, 1 point for presence of intraventricular blood, and 1 point for hemorrhage location. This score has been shown to predict short- and long-term mortality.

DIFFERENTIAL CONSIDERATIONS

Ischemic Stroke

Extra-axial collections of blood secondary to trauma can mimic stroke. An epidural or subdural hematoma can cause an altered mental status, focal neurologic signs, and rapid progression to coma. Elders, who represent the age group at highest risk for stroke, can be victims of recurrent falls that lead to chronic subdural hematomas. Carotid dissection may occur after neck trauma or sudden hyperextension and may be associated with focal neurologic signs and symptoms, as with an aortic dissection that extends into the carotid arteries. The diagnosis is supported by a compatible history or relevant findings on computed tomography (CT) imaging or magnetic resonance imaging (MRI).

Other structural lesions that may cause focal neurologic signs include brain tumors and abscesses. Air embolism should be suspected in the setting of marked atmospheric pressure changes, such as in scuba diving or during medical procedures or injuries that may allow air into the vascular system. Seizures, altered mental status, and focal neurologic findings also may be manifestations of air embolism.

Metabolic abnormalities also can mimic stroke syndromes. Hypoglycemia often is responsible for an altered mental status and is a well-known cause of sustained focal neurologic symptoms that can persist for several days. Wernicke's encephalopathy causes ophthalmoplegia, ataxia, and confusion that can be mistaken for signs of cerebellar infarction.

Migraine may present with focal neurologic findings, with or without headache. A seizure followed by Todd's postictal paralysis may mimic stroke. Bell's palsy, labyrinthitis, vestibular neuronitis, peripheral nerve palsy, and demyelinating diseases may all mimic

Box 101-2 National Institutes Of Health (NIH) Stroke Scale Scoring Form

Item	Scoring Definitions	Score
1a. *Level of consciousness (LOC)*	0 = alert and responsive 1 = arousable to minor stimulation 2 = arousable only to painful stimulation 3 = reflex responses or unarousable	
1b. *LOC-related questions:* Ask patient's age and month. Must be exact.	0 = both correct 1 = one correct (or dysarthria, intubated, foreign language) 2 = neither correct	
1c. *Commands:* Open and close eyes, grip and release nonparetic hand. (Other one-step commands or mimic also acceptable.)	0 = both correct (acceptable if impaired by weakness) 1 = one correct 2 = neither correct	
2. *Best gaze:* Horizontal EOM by voluntary or doll's eye maneuver.	0 = normal 1 = partial gaze palsy; abnormal gaze in one or both eyes 2 = forced eye deviation or total paresis that cannot be overcome by doll's eye maneuver	
3. *Visual field:* Use visual threat if necessary. If monocular, score field of good eye.	0 = no visual loss 1 = partial hemianopsia, quadrantanopia, extinction 2 = complete hemianopsia 3 = bilateral hemianopsia or blindness	
4. *Facial palsy:* If patient is stuporous, check symmetry of grimace to pain.	0 = normal 1 = minor paralysis, flat NLF, asymmetrical smile 2 = partial paralysis (lower face = UMN lesion) 3 = complete paralysis (upper and lower face)	
5. *Motor arm:* Arms outstretched 90 degrees (sitting) or 45 degrees (supine) for 10 seconds. Encourage best effort. Indicate paretic limb in score box.	0 = no drift for 10 seconds 1 = drift but does not hit bed 2 = some antigravity effort, but cannot sustain 3 = no antigravity effort, but even minimal movement counts 4 = no movement at all X = unable to assess owing to amputation, fusion, fracture, and so on	L or R
6. *Motor leg:* Raise leg to 30 degrees (from supine) for 5 seconds. Indicate paretic limb in score box.	0 = no drift for 5 seconds 1 = drift but does not hit bed 2 = some antigravity effort, but cannot sustain 3 = no antigravity effort, but even minimal movement counts 4 = no movement at all X = unable to assess owing to amputation, fusion, fracture, and so on	L or R
7. *Limb ataxia:* Check finger-nose-finger, heel-shin position sense; and score only if out of proportion to paralysis.	0 = no ataxia (or aphasic, hemiplegic) 1 = ataxia in upper or lower extremity 2 = ataxia in upper *and* lower extremity X = unable to assess owing to amputation, fusion, fracture, and so on	L or R
8. *Sensory:* Use safety pin. Check grimace or withdrawal if patient is stuporous. Score only stroke-related losses.	0 = normal 1 = mild-moderate unilateral loss but patient aware of touch (or aphasic, confused) 2 = total loss, patient unaware of touch; coma, bilateral loss	
9. *Best language:* Describe cookie jar picture, name objects, read sentences. May use repeating, writing, stereognosis.	0 = normal 1 = mild-moderate aphasia (speech difficult to understand but partly comprehensible) 2 = severe aphasia (almost no information exchanged) 3 = mute, global aphasia, coma; no one-step commands	
10. *Dysarthria:* Read list of words.	0 = normal 1 = mild-moderate; slurred but intelligible 2 = severe; unintelligible or mute X = intubation or mechanical barrier	
11. *Extinction or neglect:* Simultaneously touch patient on both hands, show fingers in both visual fields, ask about deficit, left hand.	0 = normal, none detected (visual loss alone) 1 = neglects or extinguishes to double simultaneous stimulation in any modality (visual, auditory, sensation, spatial, body parts) 2 = profound neglect in more than one modality

sedimentation rate (ESR) and is confirmed by temporal artery biopsy. Collagen vascular diseases such as polyarteritis nodosa, lupus, and other types of vasculitis may cause stroke syndromes.

Venous sinus thrombosis is another cause of focal neurologic symptoms that most commonly affects the superior sagittal sinus and lateral sinuses (see Chapter 105). The diagnosis of cerebral venous thrombosis can be difficult because of the nonspecific nature of symptoms, as well as the variable time frame of symptom onset (from hours to a few weeks). Patients may have generalized headaches, nausea, vomiting, paresis, visual disturbances, depressed level of consciousness, seizures or even symptoms generally ascribed to psychiatric disorders (such as depression).[27] Depending on the location of the thrombus, physical examination of the patient may reveal papilledema, proptosis, or palsies of CNs III, IV, and VI, as well as other focal neurologic signs and symptoms.[27] Multiple risk factors predisposing affected patients to venous sinus thrombosis are recognized, including trauma, infectious processes, hypercoagulable states, low-flow states, compression of the venous sinus, dehydration, various drugs (such as androgens, “ecstasy,” and oral contraceptives), and pregnancy or the postpartum state.

Hemorrhagic Stroke

The differential diagnosis for ICH is similar to that for ischemic stroke; considerations include migraine, seizure, tumor, abscess, hypertensive encephalopathy, and trauma. Hypertensive encephalopathy and migraine also can manifest with headache, nausea, and vomiting, although focal neurologic signs are less common in these entities. With hypertensive encephalopathy, patients usually exhibit marked elevation in BP and other evidence of end-organ injury, such as proteinuria, cardiomegaly, papilledema, and malignant hypertensive retinopathy. These patients usually improve

www.ketabpezeshki.com 66485457-66963820

significantly with treatment of their hypertension. Migraines frequently are associated with an aura, and the patient often has a history of similar headaches.

Once ICH is appreciated on neuroimaging, it can be difficult to determine underlying cause. Primary ICH typically manifests as a parenchymal hematoma with new onset neurologic symptoms. Patients with hemorrhagic transformation of an ischemic stroke may have recurrence or worsening of previously established deficits. Patients with known underlying cancer, or perihematomal edema out of proportion to the hemorrhage, should be considered for hemorrhage into a metastasis or primary tumor. Younger patients with a predominantly lobar location are at higher risk for underlying aneurysm or AVM.[20] Finally, patients with known underlying venous thromboembolic risk factors may have underlying cerebral venous sinus thrombosis (CVST).

DIAGNOSTIC STRATEGIES

Ischemic Stroke

Although clinical data can help establish the diagnosis, cause, and location of the stroke, confirmatory diagnostic tests are often required to establish the final cause or to eliminate other causes for the deficits. The immediate evaluation includes a blood glucose determination, cranial imaging (CT or MRI scan), and an electrocardiogram (ECG).

An emergent noncontrast cranial CT is the standard initial imaging technique for evaluating a patient with a potential stroke. It can quickly differentiate an ischemic stroke from ICH and other mass lesions. This information is crucial to the subsequent therapeutic decisions that must be rapidly made. A CT scan can identify almost all parenchymal hemorrhages larger than 1 cm in diameter. Recent studies have a high sensitivity for the detection of SAH by CT scan.[28] In a majority of ischemic strokes, gross signs of infarction will not appear on routine CT scans for at least 6 to 12 hours, depending on the size of the infarct. However, subtle, early ischemic changes have been noted in up to 67% of noncontrast CT scans within the first 3 hours.[28] These early ischemic changes include the hyperdense artery sign (acute thrombus in a vessel), sulcal effacement, loss of the insular ribbon, loss of gray-white interface, mass effect, and acute hypodensity (Fig. 101-2). In addition, CTA can be used to identify the presence of intravascular thrombosis, vasculature dissection, or stenosis. In cases in which arterial dissection is suspected, imaging with MRA or CTA is indicated.[12]

The clinical importance of early ischemic CT findings with regard to fibrinolytic therapy within 3 hours of symptom onset is questionable because the ability of treating physicians to reproducibly identify these findings is poor and their clinical significance is questionable.[28-30] Only acute hypodensity and mass effect have been shown to be associated with an increased risk of ICH after fibrinolysis (over that in treated patients without these findings). However, these findings do not exclude appropriate patients from fibrinolytic therapy, because the chance for excellent neurologic outcome at 3 months has been found to be better with such therapy than with placebo despite the presence of such abnormalities, and the risk of symptomatic ICH, severe disability, or death at 3 months was no different between treatment groups.[29] Patients with a hyperdense artery sign and acute hypodensity of one third of the middle cerebral artery distribution tend to have a poorer prognosis; however, their outcomes are still better with tPA treatment than without such treatment.[29]

The role of MRI in the evaluation of stroke continues to evolve. MRI can visualize ischemic infarcts earlier and identify acute posterior circulation strokes more accurately than CT. In addition, recent studies suggest that it is as effective as CT in identifying ICH.[28] However, availability, difficulty in accessing critically ill

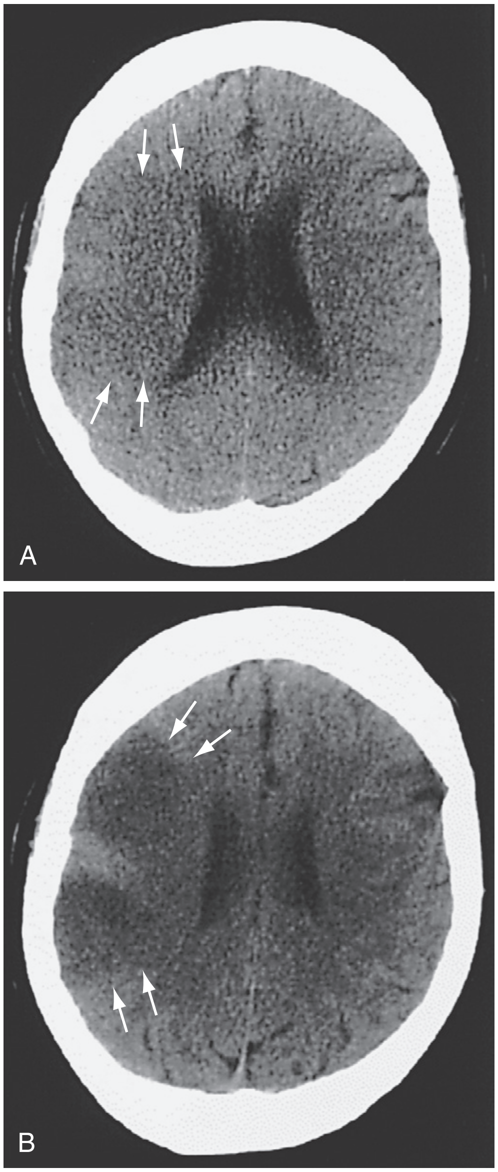

Figure 101-2. **A,** Computed tomography (CT) scan taken 2 hours and 50 minutes after a large right middle cerebral artery occlusion. There are subtle, ultra-early ischemic changes, including loss of the gray-white interface *(arrows)* and subtle evidence of sulcal effacement. **B,** CT scan of same patient approximately 8 hours after symptom onset shows acute hypodensity *(arrows)* and more prominent sulcal effacement.

patients, and scan time limit the use of MRI in acute stroke. Advances in MRA technology have allowed a noninvasive method of demonstrating large-vessel occlusions of the anterior and posterior circulation, though small intracranial vascular occlusions may not be readily apparent. With the improvements in MRI and MRA speed and resolution, some stroke centers are replacing CT protocols with limited "stroke protocol" MRI or MRA as the initial imaging modality of choice. The choice of initial cranial imaging modality is highly dependent on the speed with which these scans can be performed and interpreted at each individual center.

Diffusion-weighted imaging (DWI) and perfusion-weighted imaging (PWI) are MRI techniques that take minutes to perform and may allow differentiation between reversible and irreversible neuronal injury. In one study of patients with DWI-PWI mismatch, 30-day clinical outcomes were better after early reperfusion than without such early reperfusion (56% and 19%, respectively).[31] Of importance, however, early reperfusion in patients without

www.ketabpezeshki.com 66485457-66963820

DWI-PWI mismatch did not result in a favorable outcome. Other potential imaging modalities include CTA and perfusion scans. In CTA, a CT scan is enhanced by an intravenous contrast agent to better define the vasculature of the brain. Areas of vascular stenosis and occlusion can be visualized with this technique. This information can then be used by interventionalists to determine whether a lesion is amenable to intra-arterial thrombolysis or mechanical retrieval. Also requiring intravenous contrast, perfusion CT scans can reveal perfusion deficits within different regions of the brain. In addition, CTA and perfusion CT can differentiate reversible from irreversible ischemic insults.[28]

An ECG is indicated in all patients with acute ischemic stroke because atrial fibrillation and acute MI are associated with up to 60% of all cardioembolic strokes. The hematologic evaluation includes a complete blood count with platelet count, prothrombin time (including international normalized ratio), partial thromboplastin time, and serum glucose measurement. A toxicologic screen and cardiac isoenzyme assay should be considered if appropriate. Elevated blood viscosity, even when hematocrit levels are not frankly polycythemic, can affect blood flow and prognosis. A platelet count can identify thrombocytosis or thrombocytopenia, which may precipitate a thrombosis or hemorrhage. Coagulation studies are especially helpful to guide management for patients in whom anticoagulation is being considered or for patients with a hemorrhagic stroke. Cocaine or amphetamine ingestion should be considered with either an ischemic or hemorrhagic stroke in patients younger than 40 years of age.

Other ancillary diagnostic tests to consider include an echocardiogram, carotid duplex scan, and angiogram. Some centers are performing these studies as part of a TIA observation unit protocol in the ED. An echocardiogram can identify a mural thrombus, tumor, patent foramen ovale, or valvular vegetation in those patients in whom a cardioembolic stroke is suspected. An echocardiogram also should be considered in patients with no obvious cause for their stroke. Carotid duplex scanning may be helpful in patients with known or suspected high-grade carotid stenosis with worsening neurologic deficit or crescendo TIAs.[28,32] These patients may be candidates for heparinization or emergent carotid endarterectomy. Carotid duplex studies can accurately identify carotid artery stenosis with occlusion of more than 60% vessel diameter, but an angiogram is required to distinguish 95% stenosis from a complete occlusion. Finally, angiography can demonstrate stenosis or occlusion of both large and small blood vessels of the head and neck. It can detect subtle abnormalities, such as with dissection, that may not be demonstrated with other imaging techniques.

Hemorrhagic Stroke

The hematologic evaluation for the patient with hemorrhagic stroke should be performed in the same manner as for the patient with ischemic stroke. Particular attention should be directed to uncovering the presence of a coagulopathy. A drug screen should be obtained to evaluate for use of sympathomimetics if substance abuse is suspected. Increased sympathetic outflow secondary to the hemorrhage may lead to an increase in dysrhythmias. Dysrhythmias also may signal impending brainstem compression from an expanding hemorrhage.

As in ischemic stroke, the cranial CT scan is the diagnostic test of choice to evaluate for an ICH.[3] The noncontrast CT scan will reliably diagnose patients with clinically relevant acute ICH. Hemorrhages that are several days old may not be as apparent as acute hemorrhages, and appear as isodense regions.

Also, as with ischemic stroke, advanced neuroimaging modalities are gaining favor in ICH. First, CTA produces high-quality images of the larger arterial vessels and can help exclude secondary causes such as aneurysm, AVM, or fistula. In addition, some patients with primary ICH show contrast extravasation on CTA, and such patients are at particularly high risk of ongoing bleeding and hematoma expansion. Second, a venous phase can be added to this study (CT venography [CTV]) to evaluate for CVST. Third, MRI can help detect underlying lesions such as tumor and may offer better resolution for evaluating perihematomal edema. Use of gradient-echo imaging (GRE) provides the ability to detect white matter hyperintensities and previous small ICHs (microbleeds), which can both guide the clinician as to the underlying cause of ICH and predict risk of future hemorrhage. Fourth, MRA and magnetic resonance venography (MRV) can be used in place of CTA and CTV for appropriate patients. Finally, digital subtraction angiography (DSA) remains (in many centers) the gold standard to rule out an underlying vascular abnormality.

STROKE MANAGEMENT

Ischemic Stroke

With the recent focus on rapid recognition, evaluation, and treatment of stroke, many hospitals have attempted to streamline the care of these patients to meet recommended time goals (Table 101-3). This has led to the development of various stroke protocols, critical pathways, and acute interventional stroke teams that often are deployed in the field before the patient even arrives at the ED.

In the prehospital setting, the focus should be on maintenance of the ABCs (airway, breathing, and circulation), rapid identification, early hospital notification, and rapid transport.[33] Although it is unusual for patients with ischemic stroke to be unresponsive on presentation, their ability to communicate may be altered secondary to dysphasia. After an ischemic stroke, patients usually can maintain their airway unless the brainstem is affected or unless significant cerebral edema is compressing the opposite hemisphere. Patients with intact protective airway reflexes should receive oxygen if they are hypoxic (oxygen saturation less than 95%),[33] and a monitor and intravenous line should be established.

Overhydration should be avoided to prevent cerebral edema. By contrast, dehydration may lead to decreased cerebral perfusion, and saline infusion should be given if dehydration is suspected. Dextrose-containing solutions should be avoided in normoglycemic patients suspected of having had a stroke because elevated blood glucose levels may worsen an ischemic deficit. Out-of-hospital personnel should attempt to rapidly ascertain the patient's blood sugar. If this is not possible, glucose should be given only to diabetic patients in whom hypoglycemia is strongly suspected. Electrocardiographic monitoring is recommended to identify life-threatening arrhythmias and atrial fibrillation.[33]

The circumstances surrounding the stroke as well as concomitant medical conditions should be ascertained. A key part of the

initial information on stroke patients is the prehospital providers' documentation of the exact time the patient was last seen to be neurologically normal and the level of neurologic functioning. This is especially important because reversible defects may completely resolve by the time the patient has arrived at the hospital. The level of consciousness, gross focal motor deficits, difficulty with speech, clumsiness, facial asymmetry, and any other focal deficits should be noted. Prehospital stroke scales have been developed to assist in differentiating patients who have had a stroke from those who have not and to identify potential candidates for fibrinolytic therapy.[33] Early recognition, notification, and transport by emergency medical services (EMS) and other out-of-hospital personnel have been shown to be valuable in enabling early treatment.[33]

In the ED setting, the ABCs should be reassessed on an ongoing basis, because patients may experience rapid deterioration, even with subacute stroke. Some stroke patients are found at home 1 or 2 days after the event has occurred and may have concomitant illnesses, such as aspiration pneumonia, dehydration, hypothermia, rhabdomyolysis, or myocardial ischemia. Fever necessitates a thorough evaluation to identify the source of infection, followed by prompt institution of appropriate treatment. As supported by strong evidence, even minor degrees of hyperthermia will result in worsening of the neurologic injury.[33]

Blood Pressure Management

The management of BP in patients with acute ischemic stroke and TIA is controversial because of limited data. Current guidelines for the management of hypertension in patients with acute ischemic stroke recommend that antihypertensive treatment be reserved for those with markedly elevated BPs, unless fibrinolytic therapy is planned or specific medical indications are present.[7] These medical indications include (1) acute MI, (2) aortic dissection, (3) true hypertensive encephalopathy, and (4) severe left ventricular failure.

Oral or parenteral agents are withheld unless the patient's systolic pressure is greater than 220 mm Hg, diastolic pressure is greater than 120 mm Hg, or mean arterial pressure (MAP) is greater than 130 mm Hg (Box 101-5). If parenteral agents are used, labetalol or nicardipine is favored because of ease of titration and limited effect on cerebral blood vessels. Sublingual nifedipine or sublingual nitroglycerin is not recommended because either agent can produce a precipitous drop in BP.[7]

If fibrinolytic therapy is planned, stringent control of BP is indicated to reduce the potential for intracranial hemorrhage after the thrombolytic is administered (Box 101-5).[7]

Thrombolytic therapy is not recommended for patients whose systolic pressure is consistently higher than 185 mm Hg or whose diastolic pressure is 110 mm Hg at the time of treatment. Simple measures can be used to try lowering BP below this level. Recommended approaches include the use of nitroglycerin paste and one or two doses of intravenous labetalol 10 to 20 mg. If more aggressive measures are required to reduce BP below 185/110 mm Hg, the use of tPA is not recommended. Once thrombolytic therapy has been initiated, BP must be monitored closely and hypertension treated aggressively.

Just as problematic as high BP can be, low BP can be quite detrimental to patients with ischemic stroke.[7] Normally normotensive stroke patients with low BP or normally hypertensive stroke patients with low or even low-normal BP are given a fluid bolus to try to increase cerebral perfusion. This is especially important in patients in a dehydrated state. If initial fluid challenge is ineffective, the patient may require vasopressor therapy (e.g., with dopamine) to gradually increase MAP and improve cerebral perfusion.[7]

Box 101-5 Emergency Antihypertensive Therapy for Acute Ischemic Stroke

- Indication that patient is eligible for treatment with intravenous rtPA or other acute reperfusion intervention
  - Blood pressure level
    - Systolic >185 mm Hg or diastolic >110 mm Hg
      - Labetalol 10-20 mg IV over 1-2 min, may repeat × 1
      - *or*
      - Nitropaste 1-2 inches
      - *or*
      - Nicardipine infusion, 5 mg/hr, titrate up by 2.5 mg/hr at 5- to 15-min intervals, maximum dose 15 mg/hr; when desired blood pressure attained, reduce to 3 mg/hr
    - If blood pressure does not decline and remains >185/110 mm Hg, do not administer rtPA
- Management of blood pressure during and after treatment with rtPA or other acute reperfusion intervention
  - Monitor blood pressure every 15 min during treatment and then for another 2 hr, then every 30 min for 6 hr, and then every hour for 16 hr
  - Blood pressure level
    - Systolic 180-230 mm Hg or diastolic 105-120 mm Hg
      - Labetalol 10 mg IV over 1-2 min, may repeat every 10-20 min, maximum dose of 300 mg
      - *or*
      - Labetalol 10 mg IV followed by an infusion at 2-8 mg/min
    - Systolic >230 mm Hg or diastolic 121-140 mm Hg
      - Labetalol 10 mg IV over 1-2 min, may repeat every 10-20 min, maximum dose of 300 mg
      - *or*
      - Labetalol 10 mg IV followed by an infusion at 2-8 mg/min
      - *or*
      - Nicardipine infusion, 5 mg/hr, titrate up to desired effect by increasing 2.5 mg/hr every 5 min to maximum of 15 mg/hr
    - If blood pressure not controlled, consider sodium nitroprusside

Acute Drug Therapy

To date, only the use of intravenous tPA has been approved by the U.S. Food and Drug Administration (FDA) for treatment of patients with acute ischemic stroke. These recommendations initially were based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) trial, although subsequent analysis of other studies has supported its use.[34-36] Concern previously emerged regarding the safety of the use of tPA in community practice.[37] However, a meta-analysis of non–trial-related use of tPA (N = 2639) in community practice demonstrates efficacy and safety for tPA similar to that reported in the NINDS trial.[38] The current recommendation for recombinant tPA (rtPA) is that it be administered intravenously at a dose of 0.9 mg/kg to a maximum of 90 mg (10% of the dose given as a bolus followed by an infusion lasting 60 minutes). Although the initial recommended time window for intravenous tPA administration was 3 hours since the patient was last known to be at his or her neurologic baseline, a subsequent study has demonstrated the usefulness of intravenous tPA at 3 to 4.5 hours in a carefully selected subgroup of acute

Box 101-6 Fibrinolytic Therapy for Acute Ischemic Stroke in the 0- to 3-Hour Time Window: Inclusion and Exclusion Criteria

Inclusion Criteria

1. Age 18 years or older
2. Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit
3. Time of symptom onset well established to be less than 180 minutes before treatment would begin

Exclusion Criteria

1. Evidence of intracranial hemorrhage on noncontrast head CT
2. Only minor or rapidly resolving stroke symptoms
3. High clinical suspicion of subarachnoid hemorrhage even with normal CT findings
4. Active internal bleeding (e.g., gastrointestinal or urinary bleeding within last 21 days)
5. Known bleeding diathesis, including but not limited to:
   - Platelet count <100,000/μL
   - Patient has received heparin within 48 hours and had an elevated activated partial thromboplastin time (greater than upper limit of normal for laboratory)
   - Recent use of anticoagulant (e.g., warfarin sodium) and elevated prothrombin time >15 seconds
6. Within 3 months of intracranial surgery, serious head trauma, or previous stroke
7. Within 14 days of major surgery or serious trauma
8. Recent arterial puncture at noncompressible site
9. Lumbar puncture within 7 days
10. History of intracranial hemorrhage, arteriovenous malformation, or aneurysm
11. Witnessed seizure at stroke onset
12. Recent acute myocardial infarction
13. On repeated measurements, systolic pressure >185 mm Hg or diastolic pressure >110 mm Hg at time of treatment, requiring aggressive treatment to reduce blood pressure to within these limits

CT, computed tomography.

Box 101-7 Fibrinolytic Therapy for Acute Ischemic Stroke in the 3- to 4.5-Hour Time Window: Inclusion and Exclusion Criteria

Main Inclusion Criteria

Acute ischemic stroke
Age 18 to 80 years
Onset of stroke symptoms 3 to 4.5 hours before initiation of study-drug administration
Stroke symptoms present for at least 30 minutes with no significant improvement before treatment

Main Exclusion Criteria

Intracranial hemorrhage
Time of symptom onset unknown
Symptoms rapidly improving or only minor before start of infusion
Severe stroke as assessed clinically (e.g., NIHSS score >25) or by appropriate imaging techniques*
Seizure at the onset of stroke
Stroke or serious head trauma within the previous 3 months
Combination of previous stroke and diabetes mellitus
Administration of heparin within the 48 hours preceding the onset of stroke, with an activated partial-thromboplastin time at presentation exceeding the upper limit of the normal range
Platelet count of less than 100,000/mm^3
Systolic pressure greater than 185 mm Hg or diastolic pressure greater than 110 mm Hg, or aggressive treatment (intravenous medication) necessary to reduce blood pressure to these limits)
Blood glucose less than 50 mg/dL or greater than 400 mg/dL
Symptoms suggestive of subarachnoid hemorrhage, even if CT scan was normal
Oral anticoagulant treatment
Major surgery or severe trauma within the previous 3 months
Other major disorders associated with an increased risk of bleeding

CT, computed tomography.
*A severe stroke as assessed by imaging was defined as a stroke involving more than one third of the middle cerebral artery territory.
NIHSS denotes National Institutes of Health Stroke Scale, in which total scores range from 0 to 42, with higher values reflecting more severe cerebral infarcts.

ischemic stroke patients[39] (Boxes 101-6 and 101-7). Intravenous tPA is not recommended when the time of stroke onset cannot be ascertained reliably, including strokes recognized on awakening. In addition, caution is warranted in treating patients with large strokes (NIHSS score of 20 or higher) or those with early CT changes from a recent major infarction (e.g., acute hypodensity or mass effect) because they are at increased risk for symptomatic hemorrhage.[7,40] A recent study suggests that patients with mild or rapidly resolving symptoms may still benefit from the use of intravenous tPA.[25]

Intra-arterial thrombolysis is an alternative treatment for eligible patients seen beyond the 3-hour time window but within 6 hours of symptom onset.[41,42] In the Prolyse in Acute Cerebral Thromboembolism II (PROACT II) study, patients with middle cerebral artery strokes were 58% more likely than those who received a placebo to have little or no neurologic disability at 90 days when treated with intra-arterial prourokinase up to 6 hours after stroke onset.[41] In addition, the use of intra-arterial thrombolysis in patients with posterior circulation strokes and those unresponsive to initial treatment with intravenous tPA also is being evaluated and has shown favorable outcomes.[7,43-46]

Various mechanical clot retrieval devices are being investigated. The best studied is the Mechanical Embolus Removal in Cerebral Ischemia (MERCI) retrieval device. This corkscrew-like device has been shown to be successful in recanalizing intracranial lesions of the internal carotid artery and has demonstrated improved clinical outcomes and survival when compared with outcomes of patients who do not have successful recanalization of the artery.[47] Successful recanalization has been achieved when performed within an 8-hour window of symptom onset.[48,49] In 2004 the FDA approved the MERCI retrieval device for use in the setting of acute ischemic stroke.

Previous studies have focused on the use of antiplatelet agents in acute ischemic stroke. Data from two large trials involving almost 40,000 patients indicate that early use of aspirin in patients with acute ischemic stroke who were not treated with a fibrinolytic agent was associated with a small but significant reduction in rates of stroke recurrence and mortality.[50] These studies in combination suggest a number needed to treat of 77 (i.e., 77 stroke patients would need to be treated with daily aspirin therapy to prevent a poor outcome, such as death, dependency at discharge, or at 6 months after stroke, in 1 patient). The need for acute administration of aspirin in the ED is unclear, because patients were given aspirin up to 48 hours after stroke onset. Aspirin should not be given for the first 24 hours to patients who have received a fibrinolytic agent.[7]

The use of low-molecular-weight or unfractionated heparin is common in patients with acute ischemic stroke or TIAs, but its value is unclear. It may be that any reduction in risk of subsequent ischemic stroke is balanced by an increased risk of hemorrhagic stroke. To date, no studies have definitively established the efficacy

www.ketabpezeshki.com 66485457-66963820

of anticoagulants in the management of patients with acute ischemic stroke, and current AHA guidelines recommend against the routine use of heparinoids in this population.[7,51,52] However, heparin is sometimes considered in select patients at high risk for stroke progression, including patients with crescendo TIAs or TIA from a cardioembolic source, patients with a high-grade carotid artery stenosis, patients with posterior circulation TIA, and patients with evolving strokes. Heparin is recommended for the treatment of carotid and vertebral artery dissection unless a contraindication such as intracranial extension is present. If a dissection is diagnosed and the patient has no symptoms of ischemia, treatment with antiplatelet therapy alone may be an option.[13] Heparin therapy should not be initiated in patients with suspected endocarditis or in any patient until a CT scan has ruled out intracranial bleeding. Owing to the lack of consistent evidence of efficacy, the most prudent course in the ED setting is to determine the need for heparin therapy in conjunction with the patient's neurologist or the admitting physician.

General supportive care should not be overlooked. Antipyretics should be provided for patients who are febrile (while an infectious source is also sought). Hyperglycemia appears to be neurotoxic, and many patients demonstrate this finding even in the absence of known diabetes; although intensive insulin therapy is not clearly beneficial, some form of glucose control such as with sliding scale subcutaneous therapy is probably warranted.[53,54] Oral medications (and food) should be withheld until some form of swallowing assessment has been performed, given the risk of aspiration in patients with compromised swallowing function.[55] Finally, as mentioned earlier, there is some evidence favoring admission to a stroke unit.[56]

Intracerebral Hemorrhage

Overall, no specific therapy has been demonstrated to improve the outcome of patients with ICH in a phase III clinical trial. However, indirect evidence supports the value of aggressive medical care. Patients admitted to a specialized unit, patients who are expedited to the ICU, those admitted on a weekday, and those treated more aggressively appear to have better neurologic outcomes.[57-61] Therefore, even in the absence of therapies specifically proven in phase III trials, multidisciplinary care by specially trained care teams appears to provide benefit.

The patient with suspected ICH requires rapid assessment and transport to a care center with rapid neuroimaging and intensive care management facilities. Out-of-hospital management is similar to that for ischemic stroke, including determination of time of onset, concomitant medications, and application of a prehospital stroke scale.

Supportive care involving attention to airway management and perfusion is of the highest priority. Patients with hemorrhagic stroke are more likely to have an altered level of consciousness that may rapidly progress to unresponsiveness requiring emergent endotracheal intubation. After intubation, a short-acting medication for sedation should be considered, so that a neurologic examination can be repeatedly performed and the findings evaluated. Standard care includes establishing intravenous access and cardiac monitoring. Evaluation of blood glucose and appropriate dextrose and naloxone administration are essential in any patient with altered mental status.

Patients seen early after symptom onset are at high risk of ongoing bleeding. Approximately 30% of such patients will have significant hematoma expansion on presentation, leading to neurologic deterioration and worse outcome. Major therapies aimed at reducing this risk include BP reduction, anticoagulation reversal, and hemostatic therapy.

BP control is commonly performed after ICH. This intervention is controversial, as hypertension may potentiate further bleeding, but lowering BP in a patient with chronic hypertension may decrease CBF, worsening brain injury. One randomized trial found that lowering systolic BP to below 140 reduced ongoing bleeding, but there was no change in neurologic outcome, suggesting that this therapy may not provide clinical benefit in unselected patients.[62] The current consensus regarding management of ICH is to recommend antihypertensive treatment with parenteral agents for systolic pressures higher than 160 to 180 mm Hg or MAP higher than 130 mm Hg. Agents that are thought to minimize risk of ICP elevation include labetalol, esmolol, nicardipine, and hydralazine.[3]

Many patients are anticoagulated at the time of their ICH. In the absence of clinical trials, most experts believe that emergency anticoagulation reversal can minimize the risk of further bleeding. For patients on warfarin, this can be reversed with intravenous vitamin K, supplemented with either fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC).[3] Whether antiplatelet agents increase ongoing bleeding is controversial[63]; some providers transfuse platelets for those patients taking such agents.

Hemostatic therapy (treatment with procoagulant agents) was promising at one time, with a phase II trial of recombinant factor VIIa showing the ability to reduce hematoma expansion.[64] However, a phase III trial showed no clinical benefit[65]; as a result, there is no current evidence that patients with a normal underlying coagulation system will benefit from such agents.

For patients with clinical or radiographic evidence of elevated ICP, therapies aimed at lowering ICP should be considered. First, neurosurgical consultation is obtained to evaluate the benefits of an external ventricular drain (EVD) placement or hematoma evacuation. Pending consultation, a number of medical therapies aimed at decreasing ICP are available; however, these interventions should not be used prophylactically.[3] Hyperventilation can be a temporizing measure pending more definitive treatment. Mannitol moves fluid from the intracranial compartment, thereby reducing cerebral edema. Hypertonic saline (3% or 23.4%) can be used as an alternative to mannitol or in combination. Other experimental modalities include barbiturate coma and hypothermia.

Seizure activity can cause neuronal injury, elevations in ICP, and destabilization of an already critically ill patient. However, there is observational evidence that prophylactic administration of antiepileptic therapy (AED) may be harmful[3]; therefore AEDs should be reserved for patients with known or suspected seizure (or nonconvulsive seizure).

Surgical evacuation of the hematoma is not beneficial in most cases of noncerebellar ICH.[66] Selected patients with a sizable lobar hemorrhage that is proximal to the cortical surface and associated with progressive neurologic deterioration may benefit from surgical drainage. Recent studies have also suggested that minimally invasive surgery, stereotactic insertion of a catheter, may provide some benefit to selected patients.[19] For patients with cerebellar hemorrhage, surgery can be lifesaving, as the infratentorial space is much more limited and high ICP can disrupt vital brainstem functions. For this reason, many neurosurgeons will consider emergent surgery for patients with cerebellar hemorrhage within 48 hours of onset.

In cases of severe intraventricular hemorrhage or hemorrhages in the posterior fossae, the normal circulation of cerebrospinal fluid (CSF) can become interrupted, leading to the development of hydrocephalus. This condition is characterized by an abnormal rise in CSF volume. In such cases, neurosurgeons will often place a ventricular catheter. Some groups infuse thrombolytic agents through the catheter to help break up the clot and minimize the risk of hydrocephalus.[19]

Finally, as with ischemic stroke, general supportive care should be provided to minimize neuronal injury. This includes treating

www.ketabpezeshki.com 66485457-66963820

hyperthermia (such as with acetaminophen), and treating hyperglycemia with insulin.

DISPOSITION

Ischemic Stroke and Transient Ischemic Attacks

"Stroke center" definitions have been proposed, and a national certification process for primary stroke centers is now underway. In broad terms, institutional certification as a primary stroke center requires the establishment of a stroke infrastructure (such as a stroke team, stroke unit, patient care protocols, and support services including CT scanning and laboratory testing availability), as well as institutional administrative support and strong leadership.[67] In addition, recommendations have been established for comprehensive stroke centers (CSCs). CSCs are expected to have the capability to provide the full spectrum of care to patients with stroke and other cerebrovascular diseases. More specifically, CSCs should offer advanced imaging modalities, perform surgical and endovascular interventions, and maintain a core infrastructure such as a stroke unit and stroke registry.[68] The establishment of primary stroke centers (PSCs) and CSCs is intended to improve outcomes for stroke patients by providing them with a high level of coordinated care.

It has been recommended that patients with symptoms consistent with an acute stroke should be transported to emergency facilities capable of initiating fibrinolytic therapy within 1 hour of hospital arrival. At a minimum, this requires emergent CT capabilities, an institutional "acute stroke protocol," and availability of a physician knowledgeable in the use of thrombolytic therapy. Intensive care monitoring and neurosurgery capabilities should be available within 2 hours of drug initiation, either at the treating hospital or by helicopter or ground transport to an appropriate health care facility.[69]

In most cases, once the diagnosis of an acute stroke or stroke syndrome is established and the patient is stabilized, hospitalization will be necessary for further evaluation and treatment. Patients may deteriorate over the first 24 hours and require close in-hospital monitoring. Most patients can be managed on a general medical or telemetry unit, although there is evidence suggesting a benefit from admission to a stroke-specific unit (see later). Patients with large acute hemispheric strokes (associated with increased risk of herniation) or with significant posterior circulation-related changes and those treated with a fibrinolytic agent should be monitored in a step-down or intensive care unit for at least 24 hours.

Some hospitals have specialized stroke units that provide organized, multidisciplinary care to stroke inpatients. A previous evidence-based medicine review amalgamated the results of 26 trials that compared the outcomes for more than 5500 stroke patients treated in either specialized stroke units or general wards. This review found a 14% reduction in the odds of poststroke mortality for patients treated in a stroke unit compared with patients managed on a general ward (odds ratio [OR] 0.86; 95% confidence interval [CI] 0.76 to 0.98). A similar reduction was found for the composite outcomes of death or institutionalized care (OR 0.82; 95% CI 0.73 to 0.92) and death or dependency (OR 0.82; 95% CI 0.73 to 0.92). All outcomes were independent of age, sex, or stroke severity, and evidence for increase in hospital length of stay by treatment in a stroke unit was lacking.[70]

Patients with new-onset TIAs require expedited evaluation and treatment owing to the substantial short-term risk of stroke and other adverse events.[18] Emergency neuroimaging, vascular imaging (such as with a carotid Doppler study, MRA, or CTA), electrocardiography, and basic blood tests should be performed. A medically or surgically treatable cause for TIAs (e.g., high-grade carotid stenosis, mural thrombus) should be sought, which would require in-hospital treatment such as anticoagulation, stenting, or carotid endarterectomy. In many centers, patients require admission to receive this workup. However, some centers have developed ED observation unit protocols or rapid outpatient TIA clinics to ensure an expedited evaluation.[71] One commonly used tool available to help select which TIA patients are at highest risk (and thus likely should be admitted) versus those at lowest risk (who might therefore be safe for expedited outpatient evaluation) is the ABCD2 score (Box 101-8).[72,73] In addition, most patients without a contraindication will be started on appropriate antithrombotic therapy in the ED after consultation with a neurologist.

Box 101-8 ABCD2 Score

Risk Factor	Points
Age >60 years	1
Initial BP >140/90	1
Unilateral weakness	2
Speech impairment	
Without weakness	1
Symptoms 10-59 min	1
Symptoms ≥60 min	2
History of diabetes	1

Result
0-3 = low risk (1% risk of stroke in 48 hours)
4-5 = moderate risk (4.1% risk of stroke in 48 hours)
≥6 = high risk (8% risk of stroke in 48 hours)

BP, blood pressure.

Hemorrhagic Stroke

The majority of patients with an acute hemorrhagic stroke should be admitted to an intensive care unit in which specialty consultation is available. If this is unavailable at the evaluating institution, the patient should be transported to an appropriate institution.

KEY CONCEPTS

- Patients with signs and symptoms of an acute ischemic stroke within 4.5 hours of the last time they were known to be at their neurologic baseline should be evaluated for thrombolytic therapy with the appropriate inclusion and exclusion criteria for the 0- to 3-hour time window or the 3- to 4.5-hour time window (see Table 101-3).
- Carotid Doppler, MRA, or CTA studies are recommended before discharge of a patient with TIA from the ED.
- Overly aggressive blood pressure management should be avoided in patients with acute ischemic stroke.
- Accurate identification of the last time a patient was known to be at his or her neurologic baseline should be documented in all patients with stroke.
- Assessment of gait is essential to rule out posterior circulation stroke in patients with vertigo.
- The possibility of carotid or vertebral dissection should be considered in young patients with stroke and in patients with headaches and neck pain with acute stroke.

Chapter 102

Seizure Disorders

Jason T. McMullan, Evelyn H. Duvivier, and Charles V. Pollack Jr.

PERSPECTIVE

A *seizure* is the clinical manifestation of excessive, abnormal cortical neuron activity. The physical manifestation depends on the area of brain cortex involved and, to a lesser extent, on the specific underlying abnormality. *Ictal event* is the more general term used to describe the seizure or seizure-like episode. Patients who have recurring seizures without consistent provocation have *epilepsy,* a term that encompasses many disparate clinical syndromes. Seizures may also occur as a predictable response to certain toxic, pathophysiologic, or environmental stresses; these are *reactive* or *secondary seizures,* and patients who experience these do not have epilepsy. In the United States, 10% of people experience at least one seizure in their lifetime; the cumulative incidence of epilepsy is 3%.[1]

More than 1 million patients visit U.S. emergency departments (EDs) every year for seizure care.[2] The evaluation of patients with seizures in the ED can be complex and difficult. A careful history must be elicited to determine the presence of ictal events that represent epilepsy, exposure to ictogenic stimuli (e.g., alcohol, cocaine), significant underlying illness (e.g., meningitis, hypoxemia, hypoglycemia, intracranial mass), or provocative stimuli (e.g., sleep deprivation in an epileptic). The physical examination focuses on the identification of focal neurologic abnormalities, systemic illness, and signs of toxic exposure. If the patient continues to experience seizure activity, airway protection and abortive therapy must be provided.[3] Laboratory and radiographic evaluation are guided by historical and physical findings and may be limited or unnecessary in some cases. Finally, the appropriate disposition of a patient in the ED with a seizure or with a history of a recent seizure requires an understanding of the underlying illness, likelihood of recurrence, indications for maintenance pharmacologic therapy, and state reporting regulations.

In addition to the distinction between primary (epileptic) and secondary (reactive) seizures, many other classifications of ictal events have been proposed.[4-8] Seizures are termed *generalized* or *focal (partial)* depending on the clinical manifestations. Generalized seizures result from an abnormal electrical event that simultaneously involves both cerebral hemispheres and is accompanied by loss of consciousness; in partial seizures, abnormal activity is limited to part of one cerebral hemisphere only. Generalized seizures usually are characterized by rhythmic, tonic-clonic muscle contractions, or *convulsions,* although *nonconvulsive generalized seizures* also occur. Partial seizures can be differentiated further into seizures during which cognition is maintained *(simple partial)* and seizures during which cognition is impaired *(complex partial).* The term *cognition* refers to involvement of at least two of five features—perception, attention, emotion, memory, and executive function—and replaces the previously used term *consciousness,* which is difficult to define and difficult to document.[9,10] Finally, partial seizures may become generalized *(partial with secondary generalization).*

Inexperienced witnesses may provide histories that are insufficient for accurate categorization of seizures. However, when an accurate history is available, secondary *(reactive)* seizures typically are generalized, not partial, in nature. The definitive differentiation among these classifications may require electroencephalogram (EEG) recording *during* the seizure, sometimes in association with simultaneous video recording.[11,12]

Seizures in children, as in adults, are classified as primary *(idiopathic)* and secondary (*symptomatic* or *reactive*). The term *cryptogenic* is used sometimes when seizures are thought to be secondary but no cause has been identified. The history is a vital diagnostic tool in evaluating seizures in children, as the actual seizure activity is usually not observed.

Other important terms to describe ictal events include *status epilepticus,* in which seizures are prolonged or occur serially without an intervening return to a normal neurologic condition; *spasm,* which is a specific, debilitating seizure syndrome that occurs in infants; and *myoclonus,* which refers to rhythmic, shock-like muscle contractions also typical for specific seizure syndromes. The *postictal period* is an interval after a seizure, of variable duration, usually characterized by impaired cognition but sometimes also marked by such diverse physiologic manifestations as self-limited focal motor paralysis *(Todd's paralysis)* or neurogenic pulmonary edema.

PRINCIPLES OF DISEASE

The pathophysiology of seizures at the neuronal level is incompletely understood, with most of what is known coming from animal studies in which either electrical or pharmacologic stimulation is applied directly to brain cortex. To produce generalized ictus, stimuli must be simultaneously applied to both hemispheres. Some studies show the concept of recruitment, which occurs when the initiating neurons' abnormal, increased electrical activity activates adjacent neurons and propagates until the thalamus and other subcortical structures are recruited. The clinical seizure activity typically, but not always, reflects the focus of initiation.[10,13]

What prompts such initiation is unclear. Proposed mechanisms include disruption of normal structure, whether congenital, maturational, or acquired (as with scar tissue), and disruption of local metabolic or biochemical function. The latter mechanism is better understood because the roles of two neurotransmitters—acetylcholine, which is excitatory to cortical neurons, and γ-aminobutyric acid (GABA), which is inhibitory—have been more fully characterized. In sensitive neurons, such as those at an

www.ketabpezeshki.com 66485457-66963820

ictogenic focus, subtle changes in the local concentrations of these neurotransmitters can produce sustained membrane depolarization, ultimately followed by local hyperpolarization and recruitment. Recruitment may follow contiguous paths or extend along diverse integrated circuits that are deep and cross the midline.[10,13]

When the ictal discharge extends below the cortex to deeper structures, the reticular activating system in the brainstem may be affected, altering consciousness. In generalized seizures, the focus often is subcortical and midline, which explains the prompt loss of consciousness and bilateral involvement. Seizures typically are self-limited; at some point, the hyperpolarization subsides and the electrical discharges from the focus terminate. This termination may be related to reflex inhibition, loss of synchrony, neuronal exhaustion, or alteration of the local balance of acetylcholine and GABA in favor of inhibition.[10]

The systemic manifestations of convulsive ictal activity include hypertension, tachycardia, tachypnea, and hyperglycemia from sympathetic stimulation. With more prolonged convulsions, skeletal muscle damage, lactic acidosis, and, rarely, frank rhabdomyolysis may ensue.[10,14,15] Autonomic discharge and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting (with significant aspiration risk), tongue biting, and airway impairment.

CLINICAL FEATURES

Primary Seizures in Adults

Primary ictal events in adults may have a genetic origin or may be idiopathic. Onset is typically during childhood or adolescence, but occasionally idiopathic seizures may begin de novo in adulthood. Because idiopathic seizures are rare, a first-time seizure in an adult requires a thorough evaluation.

Focal seizures in adults may be classified as simple partial or complex partial. Simple partial seizures are limited in electrical focus to one cerebral hemisphere and do not cause loss of cognition. Although the specific function of the initiating neurons determines the clinical manifestation of the ictal event (i.e., motor, somatosensory, special sensory, autonomic, or psychic), such clinical manifestations are not sufficiently specific for anatomic localization without an EEG. Typical features of simple partial seizures include focal clonic movements; paresthesias; visual, auditory, olfactory, or gustatory experiences; sweating and flushing; dysphasia; a sense of déjà vu; or a sense of unwarranted fear.[10,13] Motor signs, which by definition remain ipsilateral in simple partial seizures, may spread contiguously in a stepwise fashion *(Jacksonian march)* as neuron recruitment occurs in the motor cortex. There is generally no postictal state after a simple partial seizure.

Complex partial seizures are ictal events that involve impairment of cognition, either at onset or evolving from focal activity. Amnesia for the ictal event is a consistent feature of complex partial seizures, although during the episode the patient may remain responsive to the surroundings. Complex partial seizures typically involve automatisms that are specific to the affected person, such as lip smacking, repeated swallowing or uttering verbal phrases, or picking at clothing. Complex partial seizures generally are associated with an aura, such as a specific smell, taste, visual hallucination, or intense emotional feeling. In contrast with those experiencing generalized seizures, these patients may continue with ongoing motor activity, such as driving an automobile, riding a bicycle, or playing a musical instrument *(reactive automatisms)*, and they may react to their surroundings in a semi-appropriate manner.[10] Partial seizures may progress rapidly to generalized seizures. A postictal state is common after complex partial seizures and may persist for hours.[13]

Generalized seizures in adults may be convulsive or nonconvulsive. By definition, patients lose consciousness in a generalized seizure, and no aura is present. Some patients may experience a brief, vague prodrome or dysphoric state just before the ictal event. Convulsive generalized seizures are typified by the tonic-clonic, or grand mal, seizure, in which the patient loses consciousness, stiffens with generalized muscular hypertonus, and then rhythmically and violently contracts multiple, bilateral, and usually symmetrical muscle groups. The muscular force may be sufficiently vigorous to result in posterior shoulder dislocation or fractures of thoracic spine vertebral bodies; significant tongue and buccal injuries also may be incurred from biting with repeated jaw muscle contractions. Dysautonomia, including transient apnea, is a potential manifestation of convulsive generalized seizures; urinary incontinence is more common than fecal incontinence. A generalized convulsive seizure generally lasts 1 to 2 minutes and is followed by a postictal state, headache, and drowsiness that may persist for hours. This state must be differentiated from altered consciousness attributable to other causes.

Nonconvulsive generalized seizures include absence, or petit mal, seizures; myoclonic seizures; tonic seizures; and atonic seizures. Absence seizures in adults are subclassified further as *typical* or *atypical.* Typical absence ictus is characterized by the sudden cessation of normal, conscious activity, followed by a nonconvulsive, dissociative state that persists for a few seconds to several minutes before suddenly terminating. Eye movements, blinking, or automatisms may be present. There is no aura and no postictal state. If the seizure occurs midsentence, then the patient typically will resume speaking at precisely the point of interruption without awareness of the intervening event. Absence seizures typically begin in childhood but occasionally develop in adults. Atypical absence seizures are marked by more complicated motor signs, coexistence with other forms of generalized seizures, inconsistent postictal confusion, and irregular EEG abnormalities.[13]

Atonic seizures are characterized by focal diminution of muscle tone (limb or head) or generalized loss of postural tone in which the head falls forward and then the body slumps to the ground ("drop attack"), usually landing buttocks first (although this can vary depending on the axis of gravity at the time of the fall). Recovery occurs immediately, and there is either no loss or an extremely brief loss of consciousness. In *myoclonic-atonic seizures,* a brief (less than 100 msec) myoclonic jerk of muscle groups of variable anatomy occurs before the episode of atonia.[10] Because typically no postictal state is associated with these episodes, an altered level of consciousness in a patient after an atonic or myoclonic-atonic seizure should prompt an investigation for head trauma or a toxic or metabolic abnormality.

Status epilepticus is defined as serial seizure activity without interictal recovery or prolonged, continuous seizure activity. Traditionally, status epilepticus was defined as seizure activity lasting longer than 30 minutes, which is the estimated duration necessary for neuronal injury.[16,17] However, because an isolated tonic-clonic seizure rarely lasts more than a few minutes, an operational definition of status epilepticus as either a continuous seizure lasting more than 5 minutes or more than two discrete seizures without intervening recovery of consciousness has been advocated.[18] Although it is recognized that the underlying cause of status epilepticus is the predominant factor determining morbidity and mortality, prolonged seizure activity does cause neuronal injury and therefore warrants prompt abortive therapy. Furthermore, status epilepticus may become refractory to treatment over time.[17,19,20]

In some cases a patient's first seizure episode will manifest as status epilepticus. The most common cause of status epilepticus is discontinuation of anticonvulsant medication. This situation may be compounded by barbiturate withdrawal when phenobarbital therapy is abruptly discontinued. Many other causes of status epilepticus have been documented (Box 102-1).[14,16,21,22] After prolonged status epilepticus or after incomplete treatment, the patient

may exhibit very subtle manifestations of continued seizure activity, such as small-amplitude twitching of the extremities or jerking of the eyes, or any visible motor activity may cease while seizure activity detectable on the EEG continues.[23-25] Recognition of the latter scenario, termed *nonconvulsive status epilepticus,* requires a high index of clinical suspicion. Prompt treatment is essential to prevent neuronal damage; mortality approaches 30% if the seizure lasts more than an hour.[26] Nonconvulsive status epilepticus may be present in more than 9% of hospitalized patients with prolonged decreased mental status.[27]

All classes of primary seizures may recur sporadically, randomly, or predictably. Cyclic recurrence has been reported with awakening, sleep deprivation, emotional or physical stress, alcohol, and menses, among other factors. Seizures also may be triggered by specific sensory stimuli, the most common of which is visual stimulation in the form of flashing lights, such as strobe lights, television, and video games.[10,28] Seizures also can be caused by auditory, gustatory, tactile, or startle triggers that are specific to the affected person. The most common cause of recurrent primary seizures is medication noncompliance.[13,29]

Reactive Seizures in Adults

Reactive or secondary seizures do not result from genetic or idiopathic causes. The conditions that cause reactive seizures may be static (e.g., anatomic scarring), progressive (e.g., degenerative cortical disorders), or transient (e.g., acute electrolyte derangements).

Seizures Caused by Metabolic Derangements

Hypoglycemia is a common metabolic cause of reactive seizures. Ictal activity can occur when the plasma glucose level is less than 45 mg/dL, although some patients may manifest neurologic disturbances even at higher levels.[30] A rapid bedside glucose test is an integral part of the evaluation of the patient exhibiting seizure activity. Convulsive and nonconvulsive seizures and generalized and partial seizures all may occur during hypoglycemia.[31-34] Patients at the extremes of age are particularly susceptible to glucose stress during acute illness. Hypoglycemia also may result from insulin reaction, a deliberate insulin or hypoglycemic agent overdose, alcoholism, poor nutrition, and sepsis. Hypoglycemic seizures respond to glucose therapy; anticonvulsants and benzodiazepines are unnecessary. At times, however, prolonged seizures may cause hypoglycemia. Seizures that do not cease after correction of low blood glucose deserve further evaluation and treatment.

Cation derangements, notably hypernatremia and hyponatremia, hypomagnesemia, and hypocalcemia, are other common metabolic causes of ictal activity.[35,36] Hypo-osmolar and hyperosmolar states can precipitate seizures. Disorders of sodium, the primary cation in the extracellular fluid compartment and the primary determinant of serum osmolarity, are most common. Hyponatremia is the most frequently identified electrolyte disorder in hospitalized patients, and sodium levels less than 120 mEq/L often are associated with seizures.[37,38] The rate at which the sodium level decreases, and not the absolute magnitude of the decrease, determines the risk for neurologic manifestation.[37] Correcting hyponatremia should be undertaken slowly to avoid osmotic demyelination. If seizures are persistent, administration of hypertonic (3%) saline may be indicated.[37] Hypernatremia will result in cerebral edema and seizures in the setting of rapid elevation of serum sodium to greater than 160 mEq/L or during aggressive correction of subacute hyponatremia.[36,39]

Hypercalcemia reduces neuronal excitability and rarely causes seizures; significant hypocalcemia (below 7.5 mEq/L), however, is associated with ictal activity. Hypocalcemia may result from hypoparathyroidism, renal failure, or acute pancreatitis and typically is associated with hypomagnesemia, which also can precipitate seizures, particularly at serum levels less than 1 mEq/L. Hypomagnesemia is seen most often as a result of poor nutrition, especially in alcoholic patients. Patients with significant hypomagnesemia or hypocalcemia are treated empirically for both disorders.[35,36]

Nonketotic hyperosmolar hyperglycemia can be associated with seizure activity. Partial seizures, including partial status, predominate. These seizures do not respond to anticonvulsants; rather, they are best managed with gradual correction of fluid deficits and glucose excess.[40-42]

Seizures may complicate the course and treatment of renal failure.[43] Ictal activity occasionally complicates uremic encephalopathy, more commonly occurs as a result of acute fluid and electrolyte shifts during dialysis *(dialysis disequilibrium syndrome),* and can be a complication of immunosuppressive therapy after renal transplantation.

www.ketabpezeshki.com 66485457-66963820

Thyroid hormones lower seizure threshold, and consequently Graves' disease and thyrotoxicosis may occasionally manifest as seizures, including status epilepticus.[44] Seizures also occur with hypoparathyroidism as a result of secondary hypocalcemia.[14]

Seizures Caused by Infectious Diseases

Infectious diseases can cause seizures independent of a purely febrile mechanism. These seizures generally result from primary central nervous system (CNS) infections but occasionally arise from other septic sources. The most important ictogenic infections are meningitis, encephalitis, cerebral abscess, cerebral parasitosis, and human immunodeficiency virus (HIV) disease and associated opportunistic infections, with their protean CNS manifestations. Cerebral malaria is a common cause in developing countries.[45]

Seizures may result from the acute inflammatory response that occurs with bacterial or viral meningitis. During the acute course of illness, 15% of patients with bacterial meningitis will have at least one seizure,[46] and surviving patients have an increased risk of epilepsy.[47] Viral meningoencephalitides, the most common of which are caused by the herpes simplex virus, also are associated with seizures. These seizures may be generalized or partial, often recur during the acute phase of the illness, and may persist after the illness has resolved.[48]

The parasitic CNS infection neurocysticercosis is relatively common in areas of the United States where there is a population of immigrants from Latin America. Seizures complicate 50 to 90% of neurocysticercosis cases.[49] Latent syphilis can cause adult-onset seizures. Primary HIV disease of the CNS with its attendant infectious and mass lesion complications constitutes a significant cause of generalized and partial seizures. Common HIV-associated infections and conditions include toxoplasmosis, lymphoma, and the demyelinating infection progressive multifocal leukoencephalopathy.[50] Choosing an antiepileptic drug (AED) for an HIV-infected patient with seizures is done in consultation with infectious disease and neurology specialists because of the well-recognized increase in adverse effects of AEDs and the interactions between AEDs and antiviral medications.

Seizures Caused by Drugs and Toxins

The list of substances reported to cause seizures either as an idiosyncratic side effect of therapeutic use or as a manifestation of toxic overdose is extensive.[22,51] The recognition of this etiologic category is crucial in the ED setting. Seizure activity is a dire sign of toxicity and may herald the onset of life-threatening instability.

Seizures may occur after therapeutic doses of antimicrobials, cardiovascular agents, neuroleptics, and sympathomimetics.[52] Seizures also may result from exposure to plant toxins, insecticides, rodenticides, and hydrocarbons. Certain over-the-counter supplements also have been associated with seizures, either alone or through adverse interactions with prescription medications.[53,54] The most common drug-associated and toxin-associated seizures occur, however, in conjunction with illicit drugs, such as cocaine, amphetamines, and phencyclidine; with overdoses of anticholinergic agents, such as cyclic antidepressants and antihistamines; as a manifestation of withdrawal from ethyl alcohol and sedative-hypnotics; and with toxic levels and deliberate overdoses of diverse medications, including aspirin, theophylline, meperidine, isoniazid, lithium, and anticonvulsants, including phenytoin, carbamazepine, lamotrigine, and topiramate.[51,55] Standard ED therapeutic measures are usually effective for management of toxic seizures. In some cases, specific antidotal therapy is available, such as alkalinization for cyclic antidepressant and salicylate overdoses, and pyridoxine (vitamin B_6) for isoniazid overdose. Hemodialysis is the treatment of choice for serious salicylate and lithium toxicity. Dilantin administration is contraindicated in cases of ingestion because its sodium channel blocking actions can worsen the hemodynamic impact of the ingestion.[3]

Because of its prevalence in urban ED patient populations, cocaine toxicity warrants special mention. Seizures may occur after isolated recreational use or chronic abuse, after overdose, and in "body packers" and "body stuffers."[56] Cocaine-related seizures may be a manifestation of direct CNS toxicity or an indirect result of hypoxemia from cardiac toxicity.[57] Seizures in cocaine-intoxicated patients are managed as part of the overall toxic reaction, which often includes high fever, rhabdomyolysis, and cardiac arrhythmias. A benzodiazepine is the appropriate initial therapeutic agent.

Ethyl alcohol use and abuse are additional common toxic causes of seizures; up to 40% of seizure patients in the ED have alcohol-related seizures.[58] Ictal events may occur with acute inebriation but are more common during withdrawal from alcohol.[59] Withdrawal seizures are typically generalized and recurrent and begin within 6 hours of cessation of or decrease in alcohol consumption. Through a phenomenon termed *kindling,* the risk and severity of seizures increase with each episode of withdrawal. Kindling means that with each episode of alcohol withdrawal, the seizure threshold is lower. Alcoholic patients with seizures should also be evaluated for related, concomitant ictogenic problems (e.g., hypoglycemia, electrolyte derangements, head trauma, coingestion of other toxins, pregnancy). The preferred treatment for alcohol-associated seizures is with benzodiazepines, as these drugs substitute for the GABA-enhancing effect of ethanol in the CNS.

Seizures Caused by Trauma

Post-traumatic seizures can occur acutely as a result of blunt or penetrating head trauma or as a post-traumatic sequela. Immediate post-traumatic seizures occur within 24 hours of injury. Epidural, subdural, and intracerebral hematomas and traumatic subarachnoid hemorrhages all can be acutely ictogenic, particularly as intracranial pressure rises. More often, however, the onset of seizure activity is delayed for at least several hours. Early post-traumatic seizures occur within 1 week of injury, whereas late post-traumatic seizures occur after 1 week. Immediate and early post-traumatic seizures are more common in children than in adults, and children also are more likely than adults to be presented in status epilepticus in the immediate or early post-traumatic phase.[60]

The severity of head injury correlates with the likelihood of post-traumatic seizures. Although seizures rarely occur after mild traumatic brain injury, the incidence approaches 30% in patients with depressed skull fracture.[60,61] Antiepileptic drugs are recommended for prophylaxis against post-traumatic seizures occurring within the first 7 days after severe brain injury in adults; however, they have not been shown to be effective in preventing late post-traumatic seizures.[62,63]

Seizures Associated with Malignancy or Vasculitis

Seizures are a common manifestation of primary and metastatic CNS neoplasms. They also may complicate cancer treatment as a result of postsurgical scarring or chemotherapy-related electrolyte derangements, hematologic abnormalities, or immunosuppression. Although any CNS tumor can be ictogenic, low-grade and slow-growing primary neoplasms (e.g., well-differentiated gliomas and oligodendrogliomas) are implicated most commonly.[64] In such cases, seizures, which most often are partial with secondary generalization, may be the initial clinical manifestation. A new-onset seizure in a patient with a non-CNS primary malignancy, such as melanoma and tumors of the lung, breast, colon, germ

www.ketabpezeshki.com 66485457-66963820

cells, or renal cells, prompts consideration of CNS metastasis and warrants neuroimaging.

Seizures also may be the presenting manifestation of CNS vasculitis in patients with systemic lupus erythematosus and polyarteritis nodosa and are usually complex partial seizures that give a general indication of the acute inflammatory focus. Secondary generalization may also occur.[65]

Seizures Caused by Strokes, Arteriovenous Malformations, Aneurysms, and Migraines

Ischemic or hemorrhagic stroke is the cause of new-onset seizures in 40 to 54% of elderly patients.[66] The overall incidence of seizures with stroke ranges from 4 to 15%; more than one half occur within the first week after stroke. The incidence of epilepsy after stroke is 4 to 9%.[67,68] Seizures that occur acutely with stroke are thought to result from local metabolic alterations in the CNS; these events are transient, and the seizures often are focal and self-limited. Seizures that develop later are more likely to be generalized.

Convulsive seizures occur in 6 to 26% of patients with subarachnoid hemorrhage after aneurysmal rupture; 8 to 15% of patients will experience nonconvulsive seizures.[69] Seizures also occur in conjunction with unruptured cerebrovascular aneurysms and arteriovenous malformations.[70] Arteriography may be required to confirm the diagnosis; unruptured arteriovenous malformations are easier to detect on an enhanced cranial computed tomography (CT) scan than are smaller, unruptured aneurysms.

Seizures also may arise in concert with vascular headaches, either coincidentally, by migrainous activation of an epileptic focus, or after vascular headache has induced cerebral infarction that becomes an epileptic focus.[71]

Seizures Caused by Degenerative Disease of the Central Nervous System

In approximately 3% of patients with multiple sclerosis, focal or generalized seizures develop during the course of their illness. These seizures must be differentiated from the tonic spasms that may occur in multiple sclerosis.[72]

CNS degeneration associated with aging, including dementia and Alzheimer's disease, increases the risk of reactive seizures and epilepsy.[66,73] The elderly also are more likely to have other ictogenic problems (e.g., stroke, brain neoplasm, toxic and metabolic disturbances, blunt head trauma from falls). Maintenance treatment of elder patients with epilepsy often is complicated by drug-drug interactions, and breakthrough seizures may result even when patients are compliant. Although the incidence of unprovoked seizures increases after age 60 years, the management of these patients must include a thorough evaluation for causes of secondary seizures.[66]

Gestational Seizures

Seizures associated with pregnancy are divided into two categories: *gestational epilepsy,* in which hormonal and metabolic changes exacerbate underlying epilepsy or adversely influence serum levels of anticonvulsants, and *eclampsia* or *toxemia,* which is a gestational hypertensive encephalopathy manifesting with seizures, hypertension, coma, proteinuria, and edema. For the former, antiepileptic therapy should be tailored by the patient's neurologist and obstetrician to maximize seizure control and minimize the risk of teratogenic effects.[74]

Convulsive generalized status epilepticus in pregnancy jeopardizes both mother and fetus. The definitive treatment for eclamptic seizures is magnesium sulfate and immediate delivery of the fetus; benzodiazepines are useful adjuncts to magnesium. Simultaneous reduction in blood pressure with use of hydralazine, labetalol, or nifedipine is recommended.[75] Postpartum eclampsia represents 25% of eclamptic seizures, can occur up to 8 weeks after delivery, and can be seen in women without preceding preeclampsia.[76]

Psychogenic Nonepileptic Seizures

Psychogenic seizures, or pseudoseizures, are functional events that may be associated with alterations in cognition, abnormal movements and behaviors, and autonomic changes. They are not the result of abnormal CNS electrical activity. Psychogenic seizures may be primarily motor and mimic convulsive generalized seizures, including refractory status epilepticus, or they may be nonconvulsive and mimic either absence or complex partial seizures. Although certain features of convulsive psychogenic seizures may suggest the diagnosis, no clinical criteria are 100% specific; simultaneous video and EEG recordings may be required to confirm the diagnosis.[77,78]

The ED evaluation of these patients is difficult, because epilepsy and pseudoseizures can coexist in a minority of patients.[79] All but obviously functional abnormalities should be treated as true ictus pending formal neurologic evaluation. Many patients with pseudoseizures are not deliberately attempting to mislead the examining physician. The long-term treatment of patients with confirmed pseudoseizures may include direct confrontation, intensive psychotherapy, and use of a placebo.

Postictal States

The postictal state that follows most generalized seizures typically is characterized by decreased levels of arousal and responsiveness, disorientation, amnesia, and headache. These conditions may persist for only a few minutes or for many hours and may not be consistent from seizure to seizure. The most important consideration in ED management of the postictal state is to monitor and investigate the altered mental status after a seizure; otherwise, dangerous underlying metabolic or toxic abnormalities may be overlooked. At a minimum, airway positioning maneuvers, pulse oximetry, rapid glucose determination, and cardiac rhythm monitoring are necessary.

Two unusual postictal manifestations may provoke particular consternation in the ED: postictal paralysis and neurogenic pulmonary edema. Postictal paralysis, or Todd's paralysis, may follow generalized or complex partial seizures and is a focal motor deficit that may persist up to 24 hours and may be caused by transient focal cerebral hypoprofusion.[80] Weakness of one extremity or a complete hemiparesis may occur; in the latter case the patient should be safely restrained to avoid falls caused by a combination of weakness and diminished responsiveness resulting from the postictal state. Todd's paralysis is associated with a high likelihood of an underlying structural cause for the seizure.

Neurogenic pulmonary edema is a relatively common, although often subclinical, complication of any structural CNS insult, including seizure, trauma, and hemorrhage.[81] Neurogenic pulmonary edema is likely caused by centrally mediated sympathetic discharge and generalized vasoconstriction, coupled with increased pulmonary capillary membrane permeability. After a seizure, neurogenic pulmonary edema can be confused clinically and radiographically with aspiration pneumonia. Otherwise unexplained hypoxia or other clinical evidence of pulmonary congestion after a seizure prompts consideration of neurogenic pulmonary edema. Significant neurogenic pulmonary edema is managed with ventilatory support, including positive end-expiratory pressure.[82,83]

A prolonged postictal state raises clinical suspicion for nonconvulsive status epilepticus. After prolonged tonic-clonic seizures, ongoing cerebral epileptic activity may manifest with subtle motor

www.ketabpezeshki.com 66485457-66963820

movements such as twitching of the digits or face. EEG is the most definitive way to confirm the diagnosis.[26]

DIAGNOSTIC STRATEGIES

First-Time Seizures

The essential components of the seizure evaluation in the ED are discussed in Chapter 18. An accurate and thorough history of the ictal event and information about any known or potential precipitants or exposures and the patient's medical problems are obtained. A thorough physical examination, including a complete neurologic examination, is essential. Any identified focal neurologic deficits must be monitored for progression or resolution. Appropriate ancillary studies may be comprehensive, but if precipitants (e.g., hypoglycemia, intoxication, medication noncompliance) are known, studies may be comparatively limited. Frequently, the cause of the first seizure in an adult cannot be found in the ED.[84]

Although the Academy of Neurology recommends neuroimaging, by either CT or magnetic resonance imaging (MRI), for all adults with an apparently unprovoked first seizure, the usefulness of emergent imaging depends on the clinical situation.[85] An emergent cranial CT scan is indicated when a serious structural lesion is suspected on clinical grounds, including presence of a new focal deficit, persistent altered mental status, fever, recent trauma, persistent headache, history of cancer, anticoagulant use, suspicion or known history of acquired immunodeficiency syndrome (AIDS), age older than 40 years, and partial-complex seizure.[86] A reasonable approach is to obtain a brain CT scan on an outpatient, follow-up basis in patients who have recovered completely from the ictal event and in whom no apparent cause has been elucidated. However, if reliable follow-up care is unlikely or even questionable, the CT scan should be obtained in the ED to ensure its completion. In patients with known epilepsy and recurrent seizures, the same considerations apply, but in addition, epileptic patients with a change in seizure pattern, prolonged postictal state, or persistent abnormal mental status should undergo brain CT scan in the ED.

Children with seizures can be evaluated in a similar manner. Those with febrile seizures are not more likely than those with fever alone to have a serious bacterial infection. Children with afebrile seizures who are well appearing can generally be managed as outpatients. Blood tests and other diagnostics are indicated in children younger than 6 months, those who have had a prolonged seizure or postictal state, and those who have a preexisting metabolic disorder or suspected dehydration. Emergent neuroimaging is indicated for children with significant past medical histories or in cases of focal seizures in children younger than 3 years.[87,88] Children younger than 6 months may have positive, relevant brain CT findings in 50% of cases.[89]

The decision to initiate anticonvulsant therapy after a single seizure depends on the cause of the seizure. Seizures caused by structural lesions, such as stroke, tumor, or head injury, are likely to recur and may warrant antiepileptic medication. However, such patients also are likely to be admitted to the hospital if the lesion is newly discovered. For patients with a single unprovoked seizure, evidence-based recommendations are that antiepileptic therapy should not be initiated; rather, the patient should be discharged with referral for neurologic consultation.[84,86,90,93,94] The rationale for this approach is threefold. First, the diagnosis may be incorrect, especially if the seizure-like activity was not witnessed by experienced medical personnel. It is estimated that 20 to 25% of patients diagnosed as having seizures are eventually determined not to have seizures, with the most frequent alternative diagnoses being cardiovascular and psychopathologic.[95-98] Second, the patient may not have a recurrent seizure. It is estimated that less than 50% of patients who have had a single unprovoked seizure will experience a recurrent seizure within 2 years.[90,99,100] Furthermore, whereas treatment decreases the risk of early recurrent seizure, it does not affect long-term prognosis of epilepsy,[90,101-103] nor does it have an impact on patient quality of life,[104] with the exception of driving limitations, which are prolonged in a patient with recurrent seizure. Third, antiepileptic medications have side effects that may outweigh the benefit of treatment, especially in women of childbearing age, owing to the teratogenic risk of AEDs; in patients with liver, kidney, or hematologic disorders; and in patients already taking multiple medications.

Recurrent Seizures

The initial approach to stabilization of a patient with a known seizure disorder does not differ from that for a patient with new-onset seizure; this includes a rapid blood glucose determination and evaluation for precipitant causes. The most common cause of seizures in a patient with a diagnosed seizure disorder is noncompliance with medications.[29] However, supratherapeutic and toxic levels of some anticonvulsants, such as carbamazepine, phenytoin, lamotrigine, and topiramate, can also *cause* seizures.[105-110] Accordingly, it is prudent to check the serum drug level, if this test is available, before giving a full loading dose of anticonvulsants to patients on long-term therapy. Meanwhile, a thorough history and physical examination focus on intercurrent illness or trauma, drug or alcohol use, potential adverse drug-drug interactions with anticonvulsants, a recent change in anticonvulsant dosage regimens, and any change in ictal pattern or characteristics. Clinical indications dictate the selection of other laboratory or radiographic tests.

DIFFERENTIAL CONSIDERATIONS

Even when a "seizure" is witnessed in the ED, other abnormal movements and states of consciousness can be confused with ictal activity. The most common misdiagnoses are cardiovascular (syncope) and psychogenic, but other considerations in the differential diagnosis include hyperventilation and breath-holding, certain toxic and metabolic states, transient ischemic attacks, narcolepsy, and some movement disorders.[13,96,111-114]

At times the diagnosis can be difficult in a patient who is seen after an unwitnessed fall and unprovoked loss of consciousness. Syncope, whether vasodepressive (e.g., "vagal" or micturition syncope), orthostatic, or arrhythmogenic (e.g., paroxysmal ventricular tachycardia or fibrillation, long QT syndrome), may be confused with ictal events. Differentiating among these may be particularly difficult when episodes are recurrent; hence the consideration "fit versus faint." A tonic phase preceding tonic-clonic activity is not seen with syncope, and the tonic-clonic movements in patients with seizures are much more forceful and are more prolonged than the "twitches" sometimes associated with fainting. Tongue biting and urinary incontinence rarely occur with syncope but are common with seizures. Most seizures are characterized by a postictal state in which patients are confused and may complain of headache, which is not a feature of syncope. Retrograde amnesia also suggests an ictal diagnosis.

Hyperventilation syndrome can be associated with mood disturbances, paresthesias, and posturing movements of the distal extremities. Manifestations of toxic and metabolic disorders that mimic ictus include delirium tremens and alcoholic blackouts, the alteration in consciousness associated with hypoglycemia and acute intermittent porphyria, the buccolingual spasms of phencyclidine intoxication, and the tonic spasms caused by tetanus, strychnine, and camphor.[13] Nonictal CNS events, such as transient ischemic attacks, transient global amnesia, and atypical migraines, may manifest in a manner similar to absence seizures and postictal states such as Todd's paralysis. Carotid sinus hypersensitivity,

www.ketabpezeshki.com 66485457-66963820

which can result even from a tight necktie, may cause sudden falls that mimic drop attacks.[115] Narcolepsy (recurrent irresistible daytime sleepiness), especially when it occurs with cataplexy (sudden falls), may be associated with hallucinations and abnormal movements. It can be differentiated from seizure activity by the history and response to stimulation. Movement disorders, such as hemiballismus and tics, usually are associated with other neurologic problems. Finally, dissociative states such as fugue and panic attacks can be confused with seizures. An EEG is an appropriate diagnostic option in unclear cases.

MANAGEMENT

Immediate Management

The management of a patient experiencing a seizure begins with active, anticipatory airway management. In generalized ictus, the gag reflex is suppressed, and vomiting often is complicated by aspiration of gastric contents. The patient is placed in a left lateral decubitus position to lessen chances of aspiration. Dentures are removed but kept close by, as they may be needed for a good mask seal to be attained if bag-mask ventilation is required. A bite-block can be placed to protect the tongue and allow access for suctioning, but care should be taken to avoid iatrogenic trauma from forceful placement of intraoral devices.

If the patient is persistently apneic or if an unavoidable airway threat is present, endotracheal intubation is warranted for definitive protection. A benzodiazepine can be used as an induction agent in the hope that its action may terminate the seizure or obviate the need for tracheal intubation. Postintubation sedation with benzodiazepine infusion or propofol infusion is also recommended. Trismus may necessitate use of a short-acting neuromuscular blocking agent to facilitate intubation; long-acting paralytics will mask motor manifestations of ongoing seizures.

In general, the first-line pharmacologic agent for treatment of any active seizure is a parenteral benzodiazepine. Because benzodiazepines directly enhance GABA-mediated neuronal inhibition, they affect clinical and electrical manifestations of seizures. Benzodiazepines are effective in terminating ictal activity in a majority of patients and have been shown to be more effective than phenytoin in terminating status epilepticus.[116,117] Although phenobarbital appears to be as effective as the benzodiazepine lorazepam in terminating status epilepticus, the associated high risk of hypoventilation and hypotension limits its use as a first-line agent.[117]

The most commonly used benzodiazepines include diazepam, lorazepam, and midazolam (Table 102-1). All three may be used in patients of any age, and all share the following characteristics: rapid onset (seconds to minutes), relatively short duration of anticonvulsant action, a sedative effect, and the potential for hypotension and respiratory depression. Lorazepam has emerged as the drug of choice for the initial management of convulsions, because it terminates seizures rapidly (within 2 minutes) and has a longer duration of action (4-6 hours, compared with 20 minutes for diazepam), thus necessitating fewer repeat doses.[118-121] For this reason, it also is the preferred agent for control of alcohol withdrawal seizures.[122] Lorazepam is most effective when given intravenously but can also be administered intramuscularly, intranasally, intraosseously, and as a sublingual preparation for out-of-hospital control of seizures in children.[123]

An advantage of diazepam is that it is in liquid form at room temperature and is therefore available premixed in resuscitation kits, and it can be administered quickly and without a need for reconstitution by the intravenous, endotracheal, or intraosseous route. Its onset of action with intravenous administration is within 10 to 20 seconds, but there is a 50% chance of recurrent seizure within 2 hours if diazepam is used.[117] Diazepam can also be administered rectally via suppositories or a rectal gel. Rectal diazepam achieves variable success in seizure cessation, perhaps owing

Table 102-1 Medications Used in the Abortive Treatment of Status Epilepticus in the Emergency Department

MEDICATION	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Initial Therapy			
Diazepam	10 mg IV or 10-20 mg PR	0.15 mg/kg IV; 0.2-0.5 mg/kg PR (max 20 mg)	May repeat in 5-10 min; monitor respiratory status
Lorazepam	4 mg IV	<13 kg: 0.1 mg/kg IV (max 2 mg); 13-39 kg: 2 mg IV; >39 kg: 4 mg IV	Preferred intravenous benzodiazepine; may repeat in 10 min; monitor respiratory status
Midazolam	10 mg IV, IM, IN, buccally	0.2 mg/kg IV, IN (max 5 mg); 0.5 mg/kg buccal (max 5 mg); <13 kg: 0.2 mg/kg IM (max 5 mg); 13-39 kg: 5 mg IM; >39 kg: 10 mg IM	Preferred intramuscular benzodiazepine; may repeat in 10 min; monitor respiratory status
Second-Tier Treatments			
Phenytoin	20-mg/kg intravenous infusion	20-mg/kg intravenous infusion	May cause hypotension and dysrhythmia
Fosphenytoin	20-mg PE/kg intravenous infusion or 20 mg PE/kg IM	20-mg PE/kg intravenous infusion	
Valproic sodium	20-40 mg/kg IV infusion		Max dose 60 mg/kg/day
Pentobarbital	10- to 20-mg/kg intravenous bolus then 0.5-3.0 mg/kg/hr		Titrate according to EEG; intubation and hemodynamic support required
Phenobarbital	5-15 mg/kg IV bolus then 0.5-5.0 mg/kg/hr		Intubation likely required
Midazolam infusion	0.05-2 mg/kg/hr	0.5-2 mg/kg/hr	Monitor respiratory status
Propofol infusion	1-2 mg/kg intravenous bolus then 20-200 μg/kg/hr infusion		Intubation required
Isoflurane inhalation			Titrate according to EEG; intubation and hemodynamic support required

Brophy GM, et al: Guidelines for the evaluation and management of status epilepticus. Neurocrit Care 17:3-23, 2012.
EEG, electroencephalogram; *ET,* endotracheally; *IM,* intramuscularly; *IN,* intranasally; *IV,* intravenously; *PR,* rectally.

www.ketabpezeshki.com 66485457-66963820

to the dual venous drainage of the rectum. The inferior and middle rectal veins drain into the central circulation via the common iliacs, whereas the superior rectal vein flows into the hepatic portal system. Diazepam placed too deeply into the rectum would undergo first-pass metabolism in the liver, thus limiting bioavailability and clinical effect.

Midazolam's onset of action is within 1 minute; it is available in both intranasal and buccal formulations,[124] and among the benzodiazepines it has the least cardiovascular effect.[121] Midazolam is rapidly and reliably absorbed after intramuscular administration and has been shown to be as effective when given intramuscularly as intravenous lorazepam, making it a preferred medication when intravenous access has not yet been established.[125] Nonintravenous midazolam is as effective as intravenous diazepam, and buccal midazolam is superior to rectal diazepam in achieving symptom control.[126]

Second-line abortive anticonvulsant therapy consists of phenytoin and phenobarbital. Phenytoin reduces the repetitive firing of action potentials through sodium channel blockade, thereby stabilizing neuronal membranes.[10] Phenytoin neither sedates patients nor causes respiratory depression, but rapid intravenous administration of phenytoin in its propylene glycol diluent may cause hypotension and cardiac bradydysrhythmias, as well as local vascular injury, including venous thrombosis and localized tissue necrosis (purple glove syndrome).[127-129] Phenytoin's onset of action is within 10 to 30 minutes, and intravenous administration typically requires at least 20 minutes.[130] The duration of action is approximately 24 hours. Continued benzodiazepine administration is appropriate until phenytoin achieves adequate brain levels. Phenytoin is not recommended in toxin-induced seizures, as it is likely to be ineffective and may be harmful in cases of theophylline or tricyclic antidepressant ingestions.[3]

Fosphenytoin is a water-soluble prodrug form of phenytoin, with a more physiologic pH. Its main advantages are that it is not likely to precipitate during intravenous infusion and that it also can be administered intramuscularly, although the volume required for full loading by the intramuscular route may be in the range of 20 mL or more.[131] Although fosphenytoin can be infused more rapidly, the time to therapeutic concentration of the active drug is the same as for intravenous phenytoin.[132] The hemodynamic advantages of fosphenytoin over intravenous phenytoin have not proven to be significant.[133,134] Fosphenytoin use is most appropriate when intravenous access is not obtainable or when the intravenous line is of small gauge, as is often the case in children and elders.[120]

If the serum drug level of phenytoin is subtherapeutic in a patient already being treated for seizures, a loading dose can be given intravenously or orally in divided doses over 6 hours. Oral loading of phenytoin is associated with fewer adverse events than loading with either intravenous phenytoin or fosphenytoin,[134] but it is inadequate when therapeutic activity is required urgently.

Phenobarbital is similar to benzodiazepines in that it binds to and enhances the inhibitory neurotransmitter GABA, thereby acting as a CNS depressant that decreases ictal and physiologic cortical electrical activity. Sedation and depression of respiratory drive and blood pressure must be anticipated, and for this reason nonsedating phenytoin is preferred.[121] The onset of action of phenobarbital is within 15 to 30 minutes, and the duration of action is 48 hours.

Valproic acid administered intravenously has recently been recognized as a safe and effective treatment for seizures, especially in patients with allergies to phenytoin, the elderly, and patients with cardiorespiratory instability who might be at increased risk of adverse events from phenytoin.[135-137] Valproic acid administered intravenously has been shown to be as effective as phenytoin in patients with benzodiazepine-refractory status epilepticus, with fewer cardiopulmonary side effects.[138] Hyperammonemic encephalopathy after valproic acid loading has been reported and should be evaluated by obtaining the serum ammonia level in a patient who does not regain consciousness after seizure resolution.[21,139] Appropriate ED dosage regimens for the benzodiazepines, phenytoin, fosphenytoin, phenobarbital, and valproic acid are listed in Table 102-1.

While these agents are being given to abort ongoing seizure activity, ED management must include a search for underlying reversible causes. This search may prompt administration of dextrose for hypoglycemia, pyridoxine (vitamin B_6) for isoniazid overdose, sodium for hyponatremia, or magnesium for eclampsia.

Eclampsia complicates 1 in 1000 deliveries in the United States and can occur antepartum (91% of cases occur after 28 weeks of gestation), during the peripartal period, and up to 8 weeks postpartum.[140-142] Abortive treatment for eclamptic seizures is with magnesium sulfate, which is superior to both diazepam and phenytoin in limiting maternal mortality and preventing further seizures in eclampsia.[143,144] The loading dose of magnesium sulfate is 4 to 6 g, followed by an infusion of 2 g/hr for 24 hours.[75,143,144] Because hypermagnesemia may cause respiratory arrest, it is essential to monitor patients for hyporeflexia, which precedes respiratory compromise. In the uncommon event of respiratory compromise resulting from excessive neuromuscular blockade caused by magnesium sulfate, 1 g of 10% calcium gluconate is an effective reversal agent.[75] Simultaneous reduction in blood pressure in the eclamptic patient, with use of hydralazine, labetalol, or nicardipine, is recommended.[75]

Nonpregnant patients who continue having seizures in the ED despite management with benzodiazepines, phenytoin, or phenobarbital are likely to meet the clinical criteria for refractory status epilepticus. Additional therapeutic measures include use of valproate, midazolam infusion, propofol infusion, barbiturate coma, and general inhalational anesthesia. Valproate, which increases GABA concentration, may be given intravenously in status epilepticus (see Table 102-1).[23] Another alternative is the use of propofol, a nonbarbiturate anesthetic agent with hypnotic and anticonvulsant activity. Studies suggest that propofol acts at a location other than the benzodiazepine-binding site and modifies the chloride channel by a mechanism that is different from, and possibly synergistic with, those for benzodiazepines and barbiturates. Propofol usually is administered as an intravenous loading dose, followed by an infusion with continuous EEG monitoring to ensure persistent burst suppression.[145,146]

Barbiturate coma is effective in terminating seizures by acting as a GABA agonist, although it also suppresses all brainstem function. Neurologic consultation is advisable before induction of barbiturate coma in a patient with refractory status epilepticus. Expected consequences of barbiturate coma include respiratory arrest, myocardial depression, and hypotension. At the same time, intracranial pressure may be decreased, thus increasing cerebral perfusion. The preferred agent for barbiturate coma is pentobarbital (see Table 102-1). Patients who are treated with barbiturate coma require intubation and ventilatory support, continuous cardiac monitoring, and invasive hemodynamic monitoring. Pressors may be required to support the blood pressure.[147]

Inhalation anesthetics are one final alternative in the management of refractory ictus. Isoflurane and halothane are the common gases that are available. Halothane is associated with more hemodynamic and hepatotoxic complications. Isoflurane suppresses electrical seizure foci and is easily titratable. Patients managed with inhalational anesthesia require intubation and mechanical ventilation.

The role of newer AEDs, such as lacosamide and levetiracetam, in the management of status epilepticus has not yet been well established.[148,149]

The visible manifestations of convulsive ictus are extinguished by neuromuscular blockade. When a seizing patient is paralyzed

www.ketabpezeshki.com 66485457-66963820

and intubated, it cannot be assumed that pharmacologic therapy has terminated the seizure. Anticonvulsant administration is continued, and EEG monitoring of the patient is arranged. Without EEG, detection of seizure activity in a heavily sedated or paralyzed patient may be impossible.

Long-Term Management

Identifying a new-onset seizure disorder in the ED prompts consideration of the need for further management in the following three areas: pharmacologic, psychosocial, and legal. The primary dilemma is whether or not to initiate prophylactic anticonvulsant therapy after one seizure. The decision to treat should be based on (1) ensuring that the diagnosis of seizure is correct, (2) ascertaining the likelihood of seizure recurrence, (3) assessing the benefit versus risk of anticonvulsant therapy, and (4) discussing with the patient his or her approach to risk.

Even when witnessed in the ED, apparent ictal activity may not be a seizure. Diagnosing a seizure is more difficult when the event resolved before the patient's arrival at the ED and is based on witness reports. In patients diagnosed with a seizure, 20 to 25% are subsequently found to have been misdiagnosed.[150,151]

The risk of seizure recurrence is difficult to estimate in the ED setting. In patients with an initial unprovoked seizure, the 2-year risk of recurrence without treatment generally is considered to be less than 50%.[90,99,100] The presence of EEG abnormalities suggests greater risk, but this information usually is unavailable in the ED setting. Other factors associated with an increased risk of recurrence are partial (versus generalized) ictus, status epilepticus, a history of intracranial surgery or trauma, and the presence of a persistent neurologic abnormality, such as Todd's paralysis.

The presence of specific underlying conditions may affect the decision to institute long-term therapy. For example, it would be reasonable to initiate antiepileptic therapy for an initial seizure in an HIV-positive patient when the seizure is not a result of correctable factors such as drug toxicity or metabolic derangement.[50,90] Alcohol-related seizures are notoriously unresponsive to anticonvulsants. Prophylaxis against post-traumatic seizures beyond the first week after injury probably is unnecessary,[152] but the occurrence of early post-traumatic seizures should prompt at least short-term initiation of therapy.[153] Furthermore, if a patient not receiving antiepileptic therapy arrives in the ED with a second seizure, initiation of treatment is warranted because of the estimated 70% risk of recurrent events.[154]

The side effects of anticonvulsants can be debilitating for the patient (Table 102-2). These effects should be considered before such therapy is initiated, particularly in women of reproductive

Table 102-2 Important Adverse Effects and Drug-Drug Interactions of Antiepileptic Drugs

GENERIC NAME	TRADE NAME	IMPORTANT ADVERSE EFFECTS	P_{450} LIVER ENZYME METABOLIZERS*
Carbamazepine	Tegretol	Rash, leukopenia, hyponatremia, cardiac dysrhythmias (elderly), weight gain	Inducer
Clonazepam	Klonopin	Sedation, ataxia, irritability	No
Ethosuximide	Zarontin	Sedation, ataxia, nausea, anorexia	
Felbamate	Felbatol	Rare fatal aplastic anemia, hepatotoxicity, headache, anorexia, vomiting, insomnia	Inducer
Fosphenytoin	Cerebyx	Nystagmus, ataxia, sedation, headache	Inducer
Gabapentin	Neurontin	Sedation, ataxia, tremor	No
Lamotrigine	Lamictal	Hypersensitivity reaction (risk of renal failure, liver failure, DIC), rash (SJS, TEN), ataxia, headache, nausea	Inducer and inhibitor†
Levetiracetam	Keppra	Emotional lability, sedation, dizziness, infections (colds)	No
Oxcarbazepine	Trileptal	Hyponatremia, rash, dizziness, headache, fatigue	Inducer and inhibitor
Phenobarbital	Luminal	Sedation, depression, cognitive slowing, decline in libido, osteomalacia	Inducer
Phenytoin	Dilantin	Gingival hyperplasia, hirsutism, nystagmus, ataxia, sedation, nausea, osteoporosis, leukopenia, phenytoin hypersensitivity syndrome‡	Inducer
Pregabalin	Lyrica	Weight gain	No
Primidone§	Mysoline	Sedation, depression, cognitive slowing, decline in libido, acute toxicity after first dose	Inducer
Tiagabine	Gabitril	Dizziness, depression, tremor, poor concentration	No
Topiramate	Topamax	Cognitive slowing, anorexia, nephrolithiasis, paresthesias, metabolic acidosis, rare glaucoma	Inducer
Valproate	Depakote	Thrombocytopenia, tremor, weight gain, male-pattern hair loss, rare hepatotoxicity, osteoporosis	No
Zonisamide	Zonegran	Sedation, cognitive slowing, ataxia, anorexia, rash	No

Table 102-3 Medications Used for Long-Term Anticonvulsant Therapy in Adults

MEDICATION	INDICATIONS	MAINTENANCE DOSE (mg/day)*	ROUTE	THERAPEUTIC RANGE (μg/mL)	NUMBER OF DAILY DOSES
Carbamazepine	Partial and generalized seizures	800-1600	Oral	4-12	2 or 3
Clonazepam	Absence seizures	1.5-8	Oral	20-80	2 or 3
Ethosuximide	Absence seizures	750-1250	Oral	40-100	2
Felbamate	Refractory epilepsy only	2400-3600	Oral	N/A	3 or 4
Gabapentin	Partial seizures	900-3600	Oral	N/A	3
Lamotrigine	Partial, generalized, and absence seizures	100-500	Oral	N/A	2
Levetiracetam	Partial, generalized, and absence seizures	1000-3000	Oral, IV	N/A	2
Oxcarbazepine	Partial and generalized seizures	1200-2400	Oral	N/A	2
Phenobarbital	Partial and generalized seizures	90-150	Oral, intravenous	20-40	2-3
Phenytoin	Partial and generalized seizures	300-400	Oral, intravenous, intramuscular	10-20	1-3
Pregabalin	Partial seizures	150-600	Oral	N/A	2-3
Primidone	Partial and generalized seizures	750-1250	Oral	5-12	3-4
Tiagabine	Partial seizures (adjunct)	32-56‡	Oral	N/A	2-4
Topiramate	Partial and generalized seizures	200-400	Oral	N/A	2
Valproate	Partial, generalized, and absence seizures	1000-3000	Oral, intravenous	50-100	1-3
Zonisamide	Partial, generalized, and absence seizures	100-400	Oral	20-30§	1-2

N/A, not applicable.

*Adjust dose for hepatic or renal disease and with use of other medications.

‡If patient is not taking enzyme-reducing antiepileptic drugs, then daily dose should be halved (16-28).

§Some studies indicate a range of 10-50 mg/L.

age, because many anticonvulsants are teratogenic, and some precipitate failure of oral contraceptives.

In the absence of specific underlying conditions that increase risk of recurrence, evidence does not support the initiation of anticonvulsant therapy from the ED after a single unprovoked seizure in adults.[13,101,104,155] If the seizure was provoked, the decision should be based on whether the provoking factor can be corrected; if it cannot, anticonvulsant therapy should be instituted. The anticonvulsant dosage regimen for a patient with known epilepsy should be modified only in consultation with the patient's physician (Table 102-3).

Drug monotherapy is preferable in anticonvulsant regimens. Choosing the right drug depends on numerous factors, including the type of seizure, comorbid conditions, other medications the patient is taking, and the potential for pregnancy, and it is best determined in consultation with a neurologist, ideally after MRI neuroimaging and an EEG.[85] However, if an anticonvulsant is to be initiated in the ED, then the choice is among the three medications with the strongest evidence of efficacy in the treatment of a tonic-clonic seizure of either generalized onset or partial onset with secondary generalization: carbamazepine, phenytoin, and valproate.[156] It is essential to inform women of childbearing age that carbamazepine and phenytoin decrease the efficacy of oral contraceptive pills, so a second form of contraception should be used pending consultation with a neurologist. Valproate, although not altering the efficacy of oral contraceptives, carries a high risk of teratogenic effects and is therefore not an ideal first-line agent for women of childbearing years.[157,158]

The psychological and social implications of the new diagnosis of a seizure disorder for the patient can be profound. Fear of seizures and stigmatization are common; employability and insurability may be adversely affected. Although the emergency physician is not usually in a suitable position to arrange for counseling, referral to local epilepsy support groups may be helpful.

The diagnosis of a new-onset seizure disorder has legal implications as well. Each state has regulations regarding driving privileges in patients with seizures, and some states require reporting by the physician. Accordingly, ED management must ensure compliance with such regulations, including informing patients about any restrictions. Patients also should be advised to refrain from hazardous or isolated activities until cleared by their primary care physician or neurologist to participate in them. The need for a "medical alert" bracelet or other medical condition identifier should be stressed.

Finally, patients and their families should be counseled about seizure first aid, safety precautions such as avoiding swimming alone and operating dangerous machinery, and triggers for recurrence such as photic stimuli, sleep deprivation, and alcohol.

KEY CONCEPTS

- The possibility of reactive seizures should be considered in all patients in the ED with seizures or recent history of seizures, including patients with a history of epilepsy. The most common cause of reactive seizures is hypoglycemia. The most common cause of recurrent primary seizures is medication noncompliance.
- Seizures may be confused with nonictal states, including syncope, movement disorders, and psychiatric disorders.
- Neuroimaging is recommended for patients with seizures who have head trauma, persistently abnormal mental status, focal neurologic abnormality, or HIV disease.
- Primary abortive therapy for seizures in the ED setting is with a benzodiazepine; second-line agents include phenytoin and phenobarbital.

CHAPTER 103

HEADACHE DISORDERS*

Thomas Kwiatkowski and Benjamin W. Friedman

Headache is a common complaint, accounting for approximately 3 million visits to the emergency department (ED) per year in the United States.[1] In addition, many more patients present with headache as part of a constitutional illness, making the symptom of headache one of the most frequent complaints in the ED.[1]

Headache commonly is divided into *primary* and *secondary* disorders.[2] The primary headache disorders include migraine, cluster, and tension-type headaches, which represent the majority of headaches seen in clinical emergency practice.[3-5] Secondary headache disorders include a variety of organic illnesses in which head pain is a symptom of an identifiable, distinct pathologic process. To facilitate a standardized approach to headache management, the International Headache Society published a classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain.[2] This comprehensive and widely accepted system includes 14 major categories of headache disorders and uses specific operational diagnostic criteria to define each headache type (Box 103-1). Most patients presenting to an ED with headache have a benign primary headache disorder requiring only symptomatic treatment and referral. The challenge for the emergency physician is to identify the very small subset of patients who have headache as a symptom of a serious or potentially life-threatening disease.

PRIMARY HEADACHE DISORDERS

Migraine Headache

Principles of Disease

Migraine is a common, chronic, sometimes incapacitating neurovascular disease characterized by recurrent attacks of severe headache, autonomic nervous system dysfunction, and, in some patients, an aura causing visual, sensory, motor, or other neurologic symptoms.[6] It is a primary headache disorder with a genetic basis.[7]

Migraine headaches account for approximately 1 million visits to the ED per year.[8] Migraine attacks typically begin in the second decade of life and peak in prevalence in the fourth decade of life, with a 1-year period prevalence of 7% of men and 24% of women.[9] Overall, migraine is more prevalent among women (18%) than among men (6%).[9] During childhood, however, there is no gender difference in the prevalence of migraine. After menarche, a correlation between migraine and menstruation is noted in half of female migraine sufferers. After menopause, the prevalence of migraine among women decreases.[10]

Historically, migraine headaches have been considered to be vascular in origin. However, this hypothesis is no longer tenable as alterations in cerebral blood flow do not correlate with the various phases of the headache attack or vascular territories and do not explain features of an acute migraine such as premonitory mood disturbances, nausea, and osmophobia. Rather, vascular changes are now thought to be an epiphenomenon to what is a primary neurologic event.[11] Abnormal trigeminal nerve activation, possibly triggered by cortical spreading depression or, less likely, a sterile neuropeptide-induced inflammatory process, leads to pain and sensitization of higher order neurons in the brainstem and thalamus. Descending modulation is likely to be compromised as well. It is not yet known what initiates the pathophysiologic process that leads to a migraine attack. Migraine is commonly thought of in two major categories: migraine without aura, or common migraine, which is the most frequent form of migraine and accounts for approximately 80% of all cases (Box 103-2); and migraine with aura, or classic migraine, which has specific reversible neurologic symptoms that precede the actual headache (Box 103-3) and is seen less frequently.[6]

Clinical Features

Migraine is by definition a chronic and recurrent disease. The headache, characteristically, is unilateral, pulsating in quality, moderate to severe in intensity, and exacerbated by routine activities. The side of the headache can vary with individual attacks, and the headache may be bilateral in 40% of patients. The onset usually is gradual, and the attacks typically last 4 to 72 hours. Headache frequency is variable; those patients with more than 15 headache days per month are considered to have chronic migraine. Associated symptoms and signs include nausea, vomiting, anorexia, photophobia, phonophobia, osmophobia (aversion to odors), blurred vision, lightheadedness, and nasal congestion. Some patients experience premonitory cognitive impairment producing forgetfulness, irritability, and depression. Many patients have dramatic light and sound sensitivity and seek a cool, dark, and quiet room.

The aura of classic migraine consists of focal neurologic symptoms that precede and herald the migraine attack. By definition, the aura is fully reversible and typically lasts 10 to 20 minutes, although it may continue for as long as 1 hour. The most common aura is visual; features may include scintillating scotomas (bright rim around an area of visual loss), teichopsias (subjective visual image perceived with eyes open or closed), fortification spectrums (zigzagged wall of fortress slowly drifting across visual field),

*Dr. Kumar Alagappan was a contributor to this chapter in previous editions.

Box 103-2 Migraine without Aura (Common Migraine): International Headache Society Criteria

A. At least five attacks fulfilling criteria in B, C, D, and E
B. Attack lasts 4 to 72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate to severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
D. During headache, at least one of the following:
   1. Nausea or vomiting (or both)
   2. Photophobia and phonophobia
E. Not attributable to another disorder

Available at http://ihs-classification.org/en/.

Box 103-3 Migraine with Aura (Classic Migraine): International Headache Society Criteria

A. At least two attacks that fulfill criterion B
B. Presence of at least three of the following four characteristics for a diagnosis of classic migraine:
   1. One or more fully reversible aura symptoms indicating focal cerebral cortical or brainstem dysfunction (or both)
   2. At least one aura symptom developing gradually over more than 4 minutes, or two or more symptoms occurring in succession
   3. No single aura symptom lasting longer than 60 minutes
   4. Headache beginning *during* aura or *afterward,* with a symptom-free interval of less than 60 minutes (also may begin *before* aura)
C. Exclusion of related organic diseases by means of an appropriate history, physical examination, and neurologic examination with appropriate diagnostic tests

Available at http://ihs-classification.org/en/.

photopsias (poorly formed brief flashes or sparks of light), and blurred vision. Less common auras include somatosensory phenomena such as tingling or numbness, motor disturbances, and cognitive or language disorders.[6]

Ophthalmoplegic migraine is a rare syndrome associated with paresis of one or more ocular nerves, most commonly the third cranial nerve. Patients typically present with ipsilateral headache associated with extraocular muscle paresis and occasionally pupillary changes. The ophthalmoplegia or pupillary changes may last for days to weeks and rarely may become permanent. Because of the neurologic abnormalities, secondary causes including intracranial aneurysm and mass lesion should be ruled out in the absence of a clear history of recurrent identical episodes.[12]

Hemiplegic migraine is characterized by a motor aura consisting of hemiparesis or hemiplegia. The progression of the motor deficit is gradual and in most cases is accompanied by a visual, sensory, or speech disturbance. The neurologic symptoms last up to 60 minutes, followed by headache. Rarely, the motor deficit is persistent, resulting from a true migrainous stroke.[2] A familial version of hemiplegic migraine is associated with genetic mutations of ion transporters.[7]

Basilar-type migraines arise with an aura referable to the brainstem and are associated with multiple neurologic findings, including visual symptoms (often total blindness), dysarthria, tinnitus, vertigo, bilateral paresthesias, paresis, and altered level of consciousness. The symptoms are stereotypic and resolve spontaneously.[2]

Status migrainosus is a severe migraine headache that persists for more than 72 hours. Associated symptoms are debilitating, and patients require hospitalization for pain management and supportive care if they do not improve after parenteral treatment in the ED.

Many factors can trigger migraine headaches in predisposed persons. Common precipitants include sleep deprivation, stress, hunger, hormonal changes including menstruation, and use of certain drugs including oral contraceptives and nitroglycerin.[13] In addition, some patients report specific food sensitivities to chocolate, caffeine, and foods rich in tyramine, monosodium glutamate, and nitrates. Alcohol, specifically red or port wine, has also been implicated. In others, certain sensory stimuli, such as a strong glare or strong odors, loud noises, and weather changes, can trigger an attack.[6]

Differential Diagnosis

Because of the complexity of the symptoms, migraine headaches may be difficult to distinguish from secondary causes of headache. Other disorders that mimic migraine include nontraumatic subarachnoid hemorrhage caused by ruptured aneurysm or arteriovenous malformation, intracranial mass lesions, giant cell arteritis, cerebrovascular disease, and idiopathic intracranial hypertension.

Diagnostic Evaluation

Routine neuroimaging is not necessary for patients with typical recurrent migraine headaches.[14] An increasing appreciation of medical imaging–induced radiation toxicity warrants prudent use of computed tomography (CT) scanning in younger patients. Neuroimaging should be considered for older or immunocompromised patients with new-onset headaches, headaches with a progressive course, headaches worsened by Valsalva maneuver, headache causing awakening from sleep, or headaches associated with unexplained neurologic abnormalities.[14] Such patients have a higher likelihood of having a secondary cause of headache, such as tumor, arteriovenous malformation, or structural lesion. In addition, patients who present with a thunderclap or abrupt-onset headache require a lumbar puncture to rule out subarachnoid hemorrhage if findings on a CT scan are normal.[15] The description "worst headache of life" may be associated with subarachnoid hemorrhage but suffers from interobserver variability.[16]

Treatment

The pharmacologic treatment of migraine is divided into *abortive* therapies, which attempt to limit the intensity and duration of a

www.ketabpezeshki.com 66485457-66963820

Table 103-1 Selected Medications for Acute Migraine Attacks

MEDICATION	DOSE AND ROUTE ADMINISTERED	COMMENTS
Mild to Moderate		
Acetaminophen	500-1000 mg PO	Gastrointestinal upset
Aspirin	650-1000 mg PO	Gastrointestinal upset
Ibuprofen	600-800 mg PO	Gastrointestinal upset
Naproxen sodium	275-550 mg PO	Gastrointestinal upset
Moderate to Severe		
Dihydroergotamine	1 mg IV or IM; may be repeated in 1 hour	Gastrointestinal upset (pretreat with antiemetic)
Triptans Sumatriptan Sumatriptan Rizatriptan Zolmitriptan Naratriptan	 6 mg SC; may be repeated once in 1 hr if partial response 25-100 mg PO 5-10 mg PO 2.5-5 mg PO 1-2.5 mg PO	Chest pain, throat tightness, flushing Contraindicated with hypertension, coronary artery disease, peripheral vascular disease, and pregnancy Cannot be used within 24 hours of ergot use
Prochlorperazine	10 mg IV or IM; may be repeated in 30 to 60 minutes	Sedation and dystonic reaction
Metoclopramide	10 mg IV	Dystonic reaction
Droperidol	2.5 mg IV	QT prolongation; dystonic reaction
Ketorolac	30 mg IV or 30-60 mg IM	Gastrointestinal upset; avoid this medication in elderly and in patients with renal insufficiency
Morphine	4-8 mg IM or IV	Opioids less efficacious than other treatment modalities
Refractory Attack, Status Migrainosus		
Dihydroergotamine	1 mg IV q8h	Use in conjunction with antiemetic (e.g., metoclopramide, prochlorperazine)
Steroids	Various regimens	Gastrointestinal bleeding, infection, cataracts, aseptic necrosis, memory disturbances

given episode, and *prophylactic* therapies, which are intended to decrease the frequency and intensity of attacks. The goals of acute migraine therapy include rapid pain relief, minimization of headache recurrence and medication side effects, restoration of the patient's ability to function, and minimization of the use of backup and rescue medications.[17]

There are several approaches to treatment of the acute headache episode, depending on the severity of the attack (Table 103-1). The choice of agents depends on the patient's previous response to specific therapies, the existence of comorbid conditions, and the presence or absence of nausea or vomiting. Gastric stasis is common during acute migraine attacks and may limit the effectiveness of oral agents.[18]

For mild to moderate attacks, simple analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) are often effective.[19,20] In the presence of nausea or vomiting, the addition of an agent such as metoclopramide enhances the absorption and effectiveness of these medications.[21] Appropriate doses and possible side effects are listed in Table 103-1.

For moderate to severe attacks, three classes of medications can be recommended as initial parenteral therapy: the antiemetic dopamine antagonists, such as metoclopramide, prochlorperazine, and droperidol; migraine-specific agents, such as the triptans and dihydroergotamine (DHE); and parenteral nonsteroidals, such as ketorolac.

Dopamine antagonists, such as the neuroleptics prochlorperazine and chlorpromazine, and the antiemetics metoclopramide and droperidol have been shown to be highly effective as monotherapy for acute migraine attacks.[22-24] Because of their efficacy, safety, tolerability, and few contraindications, they are used by many emergency physicians as first-line therapy for many migraine patients. For this class of medication, clinical research has outpaced preclinical work, and thus a compelling mechanism of action is lacking. However, migraine pathogenesis is likely to involve dopamine pathways.[25] The most common side effects after parenteral administration include sedation, postural hypotension, and extrapyramidal symptoms, most notably akathisia, which can be treated with diphenhydramine or midazolam.[26]

DHE is administered intravenously (IV) in a dose of 1.0 mg during 2 minutes; this can be repeated in 1 hour if pain control has not been achieved. Because DHE can cause nausea and vomiting, patients should be pretreated with an antiemetic such as metoclopramide 10 mg IV or prochlorperazine 10 mg IV. Repeated administration of the intravenous form of DHE is effective in patients with status migrainosus.[27] Contraindications to use of DHE include pregnancy, breast-feeding, poorly controlled hypertension, coronary artery disease, and peripheral vascular disease. DHE should not be used if the patient has already taken any drug in the triptan class or if the patient is using macrolides or protease inhibitors.

Sumatriptan, the first-approved medication of the triptan class, a class of selective 5-HT (1B/1D) receptor agonists, is available for subcutaneous administration, and it is the most common triptan preparation used in the ED setting.[8] Other triptans available in the United States include eletriptan, almotriptan, zolmitriptan, naratriptan, frovatriptan, and rizatriptan. The initial dose of sumatriptan is 6 mg given subcutaneously, which may be repeated once in 1 hour if the patient has a partial response to the first dose. Common side effects include tingling, flushing, warm or hot sensations, heaviness in the chest, and initial worsening of the underlying headache.[28] Sumatriptan has contraindications similar to those for DHE and should not be used within hours of administration of an ergotamine-containing medication or DHE. A smaller dose of subcutaneous sumatriptan may limit side effects.[29]

www.ketabpezeshki.com 66485457-66963820

Opioid analgesics such as morphine should be reserved for patients who do not respond to any of the medications listed or have contraindications to all standard migraine therapies. Although opioids are frequently used, they have been shown to be less efficacious than other agents and are associated with frequent ED visits.[30,31]

Recurrence of migraine within 24 hours of ED discharge is common, regardless of medication administered or pain intensity at discharge.[32] Corticosteroids are effective at decreasing the rate of migraine recurrence after ED discharge, although with a number needed to treat (NNT) of 9, these medications are not necessarily indicated for all patients.[33] Oral naproxen 500 mg and sumatriptan 100 mg are reasonable treatment options for the recurrent headache.[34]

On occasion, patients do not respond to initial therapy in the ED and require hospitalization for continued pain control and supportive therapy.

Prophylactic Therapy

Prophylactic therapy is indicated for patients who have frequent attacks (more than two or three functionally disabling episodes per month), prolonged attacks lasting more than 48 hours, or attacks that are severe and debilitating. Several classes of medications are used for the prophylaxis of migraine, including beta-blockers, tricyclic antidepressants, and antiepileptic drugs.[35,36] Prophylactic therapy is best initiated in consultation with the patient's primary care provider or neurologist.

Cluster Headache

Perspective

Cluster headache is the only headache syndrome that is more common in men than in women. It typically occurs in young to middle-aged adults who smoke, with a peak incidence in the late 20s.[37] The headaches tend to occur repeatedly during a defined time interval, hence the term *cluster*. Several attacks can occur in 1 day, and a typical cluster period may last weeks to months. Several precipitating factors have been implicated, most notably the ingestion of alcohol. Stress and climatic changes may also play a role in susceptible persons.

Clinical Features

Cluster headaches occur suddenly with little warning, and multiple episodes can occur within a 24-hour period. Each headache lasts from 15 minutes up to 3 hours. The headache typically begins with a unilateral sharp, stabbing pain in the eye, which may awaken the patient from sleep. The attacks occur exclusively in the territory of the trigeminal nerve.[38] Unlike the migraineur, the patient with cluster headache predictably presents agitated and anxious, rocking, rubbing the head, and pacing. The attack subsides rapidly, often leaving the patient exhausted.

Accompanying the headache are ipsilateral autonomic symptoms such as ptosis, miosis, and forehead or facial sweating. The eye often is injected and tearing, and many patients have unilateral nasal congestion.[2]

Differential Diagnosis

Other headache disorders that mimic cluster headache include carotid artery dissection, trigeminal neuralgia, and the rare trigeminal autonomic cephalalgia paroxysmal hemicrania. Carotid dissection should be excluded as the diagnosis in patients who present with unilateral face or neck pain and Horner's syndrome. With trigeminal neuralgia, the pain peaks within seconds, lasts only a couple of minutes, and can be provoked by specific trigger points on the face or oral mucosa. The trigeminal autonomic cephalalgias are manifested by a brief unilateral headache that recurs dozens of times per day, often accompanied by the same unilateral eye and nasal symptoms as cluster.[2]

Treatment

Cluster headache is brief in duration and may resolve before a patient presents to medical attention. High-flow oxygen should be considered first-line therapy. Delivered through a non-rebreather mask at a rate of 12 L/min, it has been shown to abort the headache within 15 minutes in 78% of patients, with an NNT of 2 compared with patients who breathe room air.[39] Subcutaneous sumatriptan is also an effective therapy for acute cluster headache and should be dosed at 6 mg.[40] Larger doses do not confer much benefit, whereas smaller doses may decrease some of the medication side effects. Alternatively, octreotide or intravenous dopamine antagonists may be effective.[41,42]

Once the acute attack has been relieved, the emergency physician's work is not done. The acute attack is part of an ongoing "cluster" of headaches that likely will recur the following day. Corticosteroids have long been theorized to help break the cluster, although high-quality evidence is not available. A recommended regimen is 60 mg of prednisone daily for 10 days, followed by a 1-week taper. Verapamil, dosed at 120 mg three times a day, will decrease the frequency of attacks by the end of the first week of therapy.[43]

Tension-type Headache

Perspective

Tension-type headache is the most common recurrent headache disorder, affecting more than 50% of the population, but it is an infrequent cause of ED visits.[4,44] Women are affected slightly more frequently than men are, with peak prevalence in the fourth decade of life. These headaches typically do not cause substantial functional disability, and patients are able to continue with their normal daily activities. The median frequency of headaches is six per month, and stress and lack of sleep are implicated as triggering factors.[2,45] By definition, episodic tension-type headache lasts as little as 30 minutes and as long as 7 days.

Little is known about the pathophysiology of tension-type headache. There is no clear evidence that increased muscle activity is present, and the physical examination will reveal tender areas of the scalp and neck with both tension and migraine headaches. Despite different epidemiologic profiles, similar response to many therapeutics suggests that tension and migraine headaches may be part of a continuum with similar pathophysiologic mechanisms.[46,47]

Clinical Features

Patients typically complain of a tight, bandlike discomfort around the head that is nonpulsating and dull. They also may experience tightening of the neck muscles. A majority do not seek medical assistance because the headache usually is mild in intensity and not functionally disabling. On occasion, the discomfort can build up slowly and fluctuate in severity for several days. Unlike in migraine, the headache does not worsen with physical activity, and accompanying symptoms, such as nausea, vomiting, phonophobia, and photophobia, are unusual. Anxiety and depression may coexist with chronic tension headache, which by definition occurs more than 15 days a month and can be daily and unremitting.[2]

www.ketabpezeshki.com 66485457-66963820

Differential Diagnosis

Tension headache is the least distinct of all of the primary headache disorders, and its diagnosis is based mainly on the absence of features that would suggest another headache diagnosis. Because of this lack of specificity, the clinician often may hesitate to make this benign diagnosis without other investigations to exclude organic disease. The most common disorders mimicking tension headache are migraine, idiopathic intracranial hypertension, oromandibular dysfunction, cervical spondylosis, sinus or eye disease, and intracranial masses.[48]

Treatment

For a majority of patients with tension headaches, simple analgesics, such as acetaminophen or an NSAID, are adequate for pain control. Because tension-type headache is more common in sedentary persons, a regular exercise program may help.[37] Antiemetic dopamine antagonists may be useful therapy.[49] Patients with chronic symptoms may exhibit signs of depression or anxiety, and these patients often respond to medications and nonpharmacologic regimens that treat these conditions. Some nonpharmacologic regimens are meditation, massage, and biofeedback.

SECONDARY HEADACHE DISORDERS

Subarachnoid Hemorrhage

Principles of Disease

Subarachnoid hemorrhage (SAH) refers to extravasated blood in the subarachnoid space. Presence of the blood activates meningeal nociceptors, leading to diffuse occipital pain along with signs of meningismus. SAH accounts for up to 10% of all strokes and is the most common cause of sudden death from a stroke.[50]

Approximately 80% of patients with nontraumatic SAH have ruptured saccular aneurysms.[15] Other causes include arteriovenous malformations, cavernous angiomas, mycotic aneurysms, neoplasms, and blood dyscrasias. SAH may be caused secondarily by an intraparenchymal hematoma that dissects its way into the subarachnoid space.

The risk for aneurysmal SAH increases with age; most cases occur between the ages of 40 and 60 years.[51] In children and adolescents, aneurysms are uncommon, and when SAH occurs, it usually is secondary to an arteriovenous malformation. It is estimated that 2% of the general population harbor a berry aneurysm, and the risk of rupture may increase with aneurysmal size.[52] Other risk factors associated with SAH include hypertension, smoking, excessive alcohol consumption, and sympathomimetic drugs.[53] Increased systolic blood pressure values and long-term hypertension before aneurysm rupture seem to predict fatal SAH independently of aneurysm size or the patient's age at the time of rupture; patient gender also does not influence mortality.[54] A familial association of cerebral aneurysms with several diseases, including autosomal dominant polycystic kidney disease, coarctation of the aorta, Marfan syndrome, and Ehlers-Danlos syndrome type IV, has been described.

Of all patients presenting to the ED with a primary complaint of headache, less than 1% have SAH. Many patients with SAH die before reaching the hospital; preadmission mortality rates range from 3 to 26%.[15] Because of the significant morbidity and mortality associated with this condition and the high likelihood of clinical deterioration in patients who initially are misdiagnosed, SAH should be a primary consideration in the initial ED evaluation of all patients with nontraumatic headache. Accordingly, familiarity with its presentation is essential.

Clinical Features

A majority of patients with SAH present with a sudden, cataclysmic thunderclap headache, which often is described as "the worst headache of [their] life." The onset of headache may be associated with exertion, the Valsalva maneuver, or sexual intercourse in up to 20% of patients.[15] The headache of SAH classically peaks in intensity within seconds to minutes. Headaches that take longer to peak in intensity are less likely to be SAH.[55] Associated signs and symptoms include nausea and vomiting in approximately 75% of patients, neck stiffness in 25%, and seizures in 17%.[51] Physical findings depend on the extent of the SAH. Meningismus is present in more than 50% of patients, and up to 20% have focal neurologic abnormalities.[56] Funduscopic examination may reveal retinal or subhyaloid hemorrhages, and patients also may have an isolated third or sixth nerve palsy. Oculomotor (third) nerve compression secondary to an expanding aneurysm leads to pupillary dilation. Approximately 50% of patients with a ruptured aneurysm are restless or have an altered level of consciousness. Although a majority do not have focal neurologic signs, such signs when present may indicate the site of the aneurysm.[57]

The patient's prognosis is related to neurologic status at hospital admission. The Hunt and Hess scale stratifies patients according to their clinical signs and symptoms at the time of presentation and is predictive of outcome (Table 103-2).[58] Patients who present with a grade 1 or grade 2 hemorrhage tend to have a good prognosis. Patients with grade 4 or grade 5 hemorrhage tend to do poorly, and these patients have an altered mental status, ranging from stupor to deep coma, together with focal neurologic signs and symptoms. Patients with grade 3 hemorrhage present with drowsiness or confusion and are at risk for rapid clinical deterioration.

Diagnostic Studies

A non–contrast-enhanced head CT scan is the first-line test for the diagnosis of SAH and should be ordered emergently when this diagnosis is suspected (Fig. 103-1). For acute hemorrhage less than 24 hours old, the sensitivity of CT in identifying hemorrhage is greater than 90%; however, sensitivity decreases to approximately 50% by the end of the first week.[59] Because the sensitivity of head CT is limited, particularly as the duration of headache increases, the cerebrospinal fluid (CSF) should be examined for blood or xanthochromia, the yellowish tinting of CSF by hemoglobin breakdown products, for SAH to be ruled out definitively. A common pitfall in ED diagnostic workups of headache is to overestimate the sensitivity of the CT scan for subarachnoid blood. Alternatively, an appropriate strategy may be to perform lumbar puncture without first performing a CT scan to decrease throughput time in carefully selected young patients who have completely

Table 103-2 Hunt and Hess Clinical Grading Scale for Cerebral Aneurysms and Subarachnoid Hemorrhage

GRADE	CONDITION
0	Unruptured aneurysm
1	Asymptomatic or minimal headache and slight nuchal rigidity
2	Moderate or severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
3	Drowsiness, confusion, or mild focal deficit
4	Stupor, moderate to severe hemiparesis
5	Deep coma, decerebrate posturing, moribund appearance

www.ketabpezeshki.com 66485457-66963820

Figure 103-1. Cerebral aneurysm. Shown is a computed tomography scan of an aneurysmal subarachnoid hemorrhage in a 55-year-old woman. Subarachnoid blood can be seen within the interpeduncular and ambient cisterns and the right sylvian fissure from a ruptured aneurysm at the junction of the right carotid artery and the posterior communicating artery. (From Brisman JL: Neurosurgery for cerebral aneurysm. Emedicine, updated Sep 23, 2010. Available at http://emedicine.medscape.com/article/252142-overview#a1.)

normal physical examination findings, who are not immunocompromised, and in whom SAH is not strongly suspected.[60] This strategy may be particularly appropriate for patients in whom the differential diagnosis includes other conditions requiring a CSF analysis, such as meningitis. An alternative strategy is to perform a non–contrast-enhanced head CT scan followed by CT angiography rather than the lumbar puncture; this is reasonably sensitive and may be appropriate for patients at lower risk of disease.[59] Concerns of additional radiation exposure and contrast agent toxicity need to be weighed against the pain caused by a lumbar puncture. Finally, several published clinical decision rules can help risk stratify patients.[16,61]

After lumbar puncture is performed, interpretation of the results can be challenging because up to one third of spinal fluid analyses may be falsely positive.[62] To differentiate a traumatic lumbar puncture from SAH, the patient's CSF should be spun and the supernatant observed for xanthochromia. The yellowish pigmentation is secondary to the metabolism of hemoglobin to pigmented molecules of oxyhemoglobin and bilirubin, a process that can take up to12 hours to occur.[63] The method of comparing the red blood cell count in the first and the last tubes of CSF is less accurate, although SAH cannot be ruled out if a substantial numbers of red blood cells persist in tube 4.[15] CSF xanthochromia in association with normal findings on the CT scan is suggestive of SAH. After the diagnosis is established, angiography should be performed to study the vascular anatomy and to identify the source of hemorrhage.

A normal non–contrast-enhanced head CT scan followed by a normal spinal fluid analysis definitively rules out SAH and does not need to be followed with angiography, even in patients at high risk of disease.[64] However, this strategy does not rule out other causes of thunderclap headache that may be in the differential diagnosis, such as carotid artery dissection, cerebral venous sinus thrombosis, and reversible cranial vasoconstrictor syndrome.

Up to 90% of patients with SAH have cardiac arrhythmias or electrocardiographic abnormalities suggestive of acute cardiac ischemia, which may lead to an erroneous primary cardiac diagnosis. Typical electrocardiographic findings include ST-T wave changes, U waves, and QT prolongation.[65]

Treatment

The management of SAH is complex and includes initial resuscitation, stabilization, and emergent neurosurgical consultation. The goals of management are to treat the acute medical and neurologic complications, to prevent recurrent hemorrhage, and to forestall the ischemic complications of vasospasm. Because of an altered level of consciousness, patients with SAH of grade 3 or higher are at risk for respiratory depression and hypercapnia, which can lead to further increases in intracranial pressure (ICP); therefore, these patients may require early endotracheal intubation. Blood pressure also should be closely monitored because of the risk of continued bleeding or recurrent hemorrhage. Nimodipine, a calcium channel blocker, should be started soon after a diagnosis of aneurysmal SAH is made to lessen the likelihood of poor outcome.[66] Because nimodipine may cause transient hypotension in some patients, hemodynamic monitoring is required during its administration. The recommended dose is 60 mg by mouth or nasogastric tube every 4 hours. Antifibrinolytics (e.g., aminocaproic acid) do not improve overall outcome because the reduction in the rate of rebleeding is offset by an increase in poor outcome caused by cerebral ischemia.[67] Similarly, corticosteroids have not been demonstrated to be of benefit.[68]

Blood pressure management should be determined by the patient's clinical status with involvement of the treating neurosurgeon. The typical treatment goal is a systolic blood pressure below 160 mm Hg or a mean arterial pressure below 130 mm Hg unless vasospasm is present.[69]

Analgesics, including opioids, should be used for persistent headache. In patients who are nauseated or at risk for vomiting, antiemetics should be administered. Agitated patients require sedation, and all patients should be placed at bed rest in a quiet and dark environment. Clinically evident seizures should be treated with anticonvulsants, but the prophylactic use of these drugs is controversial.[70] A majority of patients require hemodynamic and ICP monitoring in an intensive care setting. For definitive management, endovascular coil embolization is preferable to neurosurgical clipping, but this decision is based on size, location, and morphologic features of the aneurysm as well as local expertise.[71]

Intracranial Neoplasm

Principles of Disease

Headache, the most common presenting complaint among patients with brain tumor, is reported by approximately 50% of the patients.[72] Headache is less common in older patients with brain tumors, presumably because of age-related atrophy. Headache can be caused by benign or malignant primary neoplasms of the central nervous system as well as by metastatic lesions. The most common causes of metastasis are lung and breast carcinoma, followed by malignant melanoma and carcinomas of the gastrointestinal tract.[73]

The headache of intracranial neoplasms can be caused by several mechanisms, including direct involvement of and traction on pain-sensitive structures such as meninges or larger cerebral vessels, or it may be a symptom of increased ICP. The pain patterns produced are highly variable, depending on the location and size of the mass and the structures involved. Rapidly growing tumors

www.ketabpezeshki.com 66485457-66963820

are more likely to be associated with headache. Headaches often but not always are on the same side as the tumor.[72,74]

Clinical Presentation

The typical patient presents with complaints of a worsening headache that has been present for weeks to months. The headache may have been present initially only on awakening, gradually becoming continuous. The classic triad of brain tumor headache—sleep disturbances, severe pain, and nausea and vomiting—is seen in a minority of patients.[73] Vomiting, when it is present, may be projectile and not preceded by nausea and often can be attributed to increased ICP. If increased ICP is present, the headache often is bilateral and worsened by coughing, sneezing, bending, defecation, and sexual intercourse. Other presentations of intracranial neoplasms include seizures, personality changes, and cognitive difficulties.[73]

Diagnostic Evaluation

The diagnosis of brain tumor may be suspected from the history and neurologic examination. Early in the course, patients present with just a headache and an intact neurologic examination, although the majority of intracranial neoplasms eventually will cause focal neurologic deficits. Neuroimaging with CT or magnetic resonance imaging (MRI) is the most efficient way to confirm the diagnosis. Contrast enhancement on CT often improves the identification of the underlying mass lesion and helps differentiate it from other causes, including abscess, hematoma, and vascular malformation.[75]

Treatment

Management consists of urgent referral to neurosurgery and treatment of any acute complications, including increased ICP and seizures. For patients who present with symptoms suggestive of increased ICP (e.g., headache, nausea, vomiting, confusion, weakness), treatment with steroids has been shown to be beneficial. Dexamethasone is the high-potency steroid used most often to treat edema associated with brain tumors. It has several advantages over other glucocorticoids, including a longer half-life, reduced mineralocorticoid effect, and lower associated incidence of cognitive and behavioral complications.[75] The exact dose of steroids necessary for each patient varies in accordance with histologic features, size, and location of the tumor and the amount of edema present. In general, most patients require between 8 and 16 mg of dexamethasone per day. An appropriate starting dose in the ED is 10 mg IV, followed by 4 mg every 6 hours.

Patients who have a seizure should receive anticonvulsant therapy. A multitude of antiepileptic drugs are available, and none has demonstrated superiority in this population of patients. Newer generation antiepileptics may be more tolerable. The choice of antiepileptic should be made in consultation with the specialist. Empirical or prophylactic treatment does not appear to delay or to prevent the onset of seizure activity and may expose the patient to unnecessary complications and toxicity.[76]

Giant Cell Arteritis

Principles of Disease

Giant cell arteritis, or temporal arteritis, is a systemic inflammatory process of the small and medium-sized arteries. Extracranial branches of the aortic arch and the ophthalmic vessels most commonly are involved, but the process may affect any artery in the body. The mean age at onset is 71 years, and it is rare before the age of 50 years. Women are affected more commonly than men are.[77]

Clinical Presentation

Headache is the most common initial manifestation of giant cell arteritis and occurs in more than 70% of patients with this disorder.[78] The headache often is of 2 to 3 months' duration and can be continuous or intermittent and often worsens at night or on exposure to cold. The pain may be described as sharp, throbbing, boring, or aching and usually is localized to the temporal region but may occur anywhere in the head. The physical examination may reveal tenderness over the scalp in the area of the temporal artery, with exacerbation of the pain by wearing a hat or resting the head on a pillow. Patients also may experience jaw claudication secondary to vascular insufficiency of the masseter and temporalis muscles. Systemic signs and symptoms, including fever, anorexia, and weight loss, often are present. Approximately 40% of patients develop symptoms of *polymyalgia rheumatica,* pain in their large proximal joints, with symptoms referable to the neck, torso, and lower back. Typically, pain and stiffness are worse in the morning and lessen as the day goes on.[78]

The most serious complication of giant cell arteritis is permanent visual loss, which eventually occurs in one third of untreated cases. Amaurosis fugax also can occur before permanent visual loss. Other complications include peripheral neuropathies, transient ischemic attacks, and stroke.[77]

Diagnostic Evaluation

The physical examination may reveal abnormalities of the temporal arteries, including tenderness, reduced or absent pulsations, erythema, and nodularity or swelling, best detected by light palpation just anterior and slightly superior to the tragus of the ear. Visual acuity, visual field testing, and thorough funduscopic examination should be performed.[79]

A majority of patients have a significant elevation of the erythrocyte sedimentation rate (ESR), usually to more than 50 mm/hr and often more than 100 mm/hr, although an elevated ESR is not specific for the disorder and a normal value does not rule out the diagnosis. Other abnormalities on laboratory studies include mild to moderate anemia, elevated C-reactive protein level, liver function abnormalities, and thrombocytosis. Temporal arteritis is substantially less likely in patients with an ESR below 50 mm/hr and a C-reactive protein level below 2.45 mg/dL, although patients in whom there is high suspicion of disease should be referred for biopsy even if both of these biomarkers are normal.[80,81] The diagnosis is confirmed by temporal artery biopsy. Because this is a patchy disease with skip lesions, multiple biopsy specimens of a long segment of the artery may need to be examined.

Treatment

Because of the risk of visual loss, giant cell arteritis constitutes a medical emergency, and treatment should be initiated promptly when the diagnosis is suspected. Steroids are the mainstay of therapy; the recommended initial dose of prednisone ranges from 60 mg/day. Symptomatic response usually occurs rapidly over days, although therapy should be continued for months, with close ESR monitoring.

Carotid and Vertebral Artery Dissection

Principles of Disease

Carotid and vertebral dissections are the most frequent cause of stroke in persons younger than 45 years, accounting for approximately 20% of all cases in this age group.[82] Although dissections may occur spontaneously, careful history taking frequently identifies an association with sudden neck movement or trauma

www.ketabpezeshki.com 66485457-66963820

preceding the event.[83] Reported mechanisms include neck torsion, chiropractic manipulation, coughing, minor falls, and motor vehicle collisions. Early symptoms and signs may be subtle, and delays in diagnosis are common in the absence of neurologic findings. The median delay from symptom onset to diagnosis can be several days.[84,85]

The pathologic lesion is intramural hemorrhage within the media of the arterial wall. The hematoma can be localized or extend circumferentially along the length of the vessel, resulting in partial or complete occlusion. Platelet aggregation and thrombus formation also occur, further compromising vessel patency or causing distal embolization. The timing of these events is variable, and a patient may experience symptoms of cerebral ischemia days to years after dissection.[83]

Clinical Presentation

The typical presentation of the patient with carotid or vertebral dissection is the abrupt onset of pain in the neck or face. Neurologic findings usually occur within the first few hours, but autopsy studies have shown that strokes may occur months later.[82]

Carotid Dissection. The classic triad of symptoms for carotid dissection includes unilateral headache, ipsilateral Horner's syndrome, and contralateral hemispheric findings that may include aphasia, neglect, visual disturbances, or hemiparesis. The headache is often severe and throbbing but may be subacute and similar to previous headaches. Acute severe retro-orbital pain in a previously healthy person with no history of cluster headaches is particularly suggestive of carotid dissection.[86] Most patients eventually develop signs of cerebral ischemia. Warning symptoms include transient ischemic attacks, amaurosis fugax, episodic lightheadedness, and syncope. Spontaneous dissection of the carotid artery has a favorable prognosis and recurrence is uncommon. Factors associated with a worse prognosis include old age, occlusive disease on angiography, and stroke as the initial presenting symptom.[83]

Vertebral Dissection. Vertebral artery dissections are less common than carotid dissections. The classic presentation is that of a relatively young person with severe, unilateral posterior headache and neurologic findings. The majority of patients develop a rapidly progressive neurologic deficit with symptoms of brainstem and cerebellar ischemia. Common findings include vertigo, severe vomiting, ataxia, diplopia, hemiparesis, unilateral facial weakness, and tinnitus. Spontaneous vertebral artery dissection appears to be relatively rare. Approximately 10% of patients who develop a vertebral dissection die during the acute phase, secondary to massive stroke. For patients who survive, the prognosis is usually good.[87]

Diagnosis and Treatment

Identification of patients with dissection is challenging. The emergency physician should consider the diagnosis in any young patient who presents with head or neck pain with focal neurologic findings. A non–contrast-enhanced head CT scan is often normal in uncomplicated dissection. Further imaging studies, such as CT angiography, magnetic resonance angiography, and catheter angiography, are required to confirm the diagnosis.[88] Figure 103-2 shows an example of carotid artery dissection on MRI. Duplex imaging is not sufficiently sensitive to rule out disease.[89] Treatment is aimed at prevention of stroke. It is not yet clear if early anticoagulation offers an outcome benefit over antiplatelet therapy.[90]

Cerebral Venous Sinus Thrombosis

Principles of Disease

Thrombosis of the intracranial veins and sinuses is a rare cause of stroke but tends to affect younger patients without traditional cerebrovascular risk factors.[91] Because of the significant associated morbidity, however, cerebral venous sinus thrombosis (CVST) is an important consideration in the differential diagnosis for headache in patients with suggestive signs and symptoms.

Thrombophilia is usually identified in patients with CVST, including genetic and hypercoagulable disorders, pregnancy and the puerperium, inflammatory systemic disorders including vasculitis, connective tissue disorders, and medications such as oral contraceptives. Other risk factors include head trauma, head and orofacial infections, and neurosurgical procedures.[91]

Figure 103-2. Axial T1-weighted magnetic resonance image demonstrating a crescent sign (*arrow*) in a patient with a left internal carotid artery dissection. (From Kidwell C: Dissection syndromes. Emedicine, updated Sep 19, 2011. Available at http://emedicine.medscape.com/article/1160482-overview.)

Clinical Presentation

The clinical presentation can be variable, depending on the location of the thrombosis. Common symptoms and signs include headache, seizures, decreased level of consciousness that may progress to coma, and focal neurologic deficits. Papilledema is less common with acute presentations. With cavernous sinus thrombosis, the clinical picture is dominated by ocular findings including orbital pain, proptosis, and paralysis of extraocular movements.[91]

Diagnostic Evaluation

An elevated D-dimer level is present in approximately 90% of cases of CVST and along with the clinical findings can be used to exclude the diagnosis in individual patients at low risk of disease.[92,93] The definitive diagnosis of CVST is based on neuroimaging of the area of thrombosis. CT by itself is an insensitive test, but it may reveal nonspecific late lesions, such as an infarct, hemorrhage, or edema. The key to diagnosis is to image the venous system itself. This is best accomplished by a combination of MRI to visualize the thrombosed vessel and magnetic resonance venography to detect nonvisualization of the same vessel.[94] CT angiography and venography may also be used to visualize the cerebral venous system.

Treatment

Specific treatment of CVST includes anticoagulation to prevent propagation of the thrombosis as well as complications (e.g., pulmonary embolism). In patients whose clinical condition worsens despite anticoagulation, thrombolysis or thrombectomy may be

www.ketabpezeshki.com 66485457-66963820

considered in centers with expertise in interventional procedures. Seizures should be treated with anticonvulsants.[95]

The prognosis with CVST is based on the underlying etiology, condition at time of diagnosis, and development of complications. Although overall mortality is low compared with other strokes, victims of this disease tend to be younger and healthier patients.[94]

Idiopathic Intracranial Hypertension

Principles of Disease

Although this disease is sometimes called pseudotumor cerebri or benign intracranial hypertension, the term *idiopathic intracranial hypertension* (IIH) reflects the current incomplete understanding of the pathophysiology and the fact that this disorder is not benign—a substantial minority of patients develop permanent visual loss. Compared with other headache disorders, IIH is a relatively uncommon neurologic disease seen primarily in young obese women of childbearing age. Several predisposing factors have been identified, including the use of oral contraceptives, anabolic steroids, tetracyclines, and vitamin A.[96]

Box 103-4 ICHD-II Criteria for Diagnosis of Idiopathic Intracranial Hypertension

1. Alert patient with neurologic examination that either yields normal findings or demonstrates any of the following abnormalities:
   A. Papilledema
   B. Enlarged blind spot
   C. Visual field defect (progressive if untreated)
2. Increased CSF pressure (>200 mm H_2O in nonobese patients, >250 mm H_2O in obese patients) measured by lumbar puncture in the recumbent position or by epidural or intraventricular pressure monitoring
3. Normal CSF chemistry (low CSF protein acceptable) and cellularity
4. Intracranial disease (including venous sinus thrombosis) ruled out by appropriate investigations
5. No metabolic, toxic, or hormonal cause of intracranial hypertension

Available at http://ihs-classification.org/en/.
CSF, cerebrospinal fluid; *ICHD-II,* International Classification of Headache Disorders, 2nd ed.

Pathophysiology and Clinical Features

The pathophysiologic mechanism of this disease is not understood, but it is often attributed to an imbalance between CSF production and reabsorption. The most prominent symptom is generalized headache, which often is gradual in onset and of moderate intensity. No specific localizing pattern has been documented, although in some patients the headache is worsened by eye movement. It may awaken the patient from sleep and is exacerbated by bending forward and the Valsalva maneuver, both of which impede cerebral venous return.

Visual complaints are common, and patients may experience transient visual obscuration several times a day secondary to ischemia of the visual pathways. These episodes can be followed by prolonged periods of visual loss, which can become permanent in up to 10% of patients. Patients also may complain of nausea, vomiting, dizziness, and pulsatile tinnitus. The physical examination will reveal papilledema and visual field defects, including an enlarged blind spot initially, followed by loss of peripheral vision. On occasion, a sixth nerve palsy is noted.[96]

Diagnosis

The diagnosis of IIH should not be made without neuroimaging and measurement of ICP. Diagnostic criteria are listed in Box 103-4. Venous sinus disease should be excluded in all patients with this diagnosis.[2]

Treatment

Predisposing factors (e.g., discontinuation of implicated medications) should be corrected. Symptomatic treatment often includes lowering of ICP and management of the headache. Evidence-based therapies are lacking. Acetazolamide (a carbonic anhydrase inhibitor) can be used to decrease CSF production alone or with a loop diuretic such as furosemide.[97] Steroids also have been used, although their mechanism of action is unclear. Prolonged therapy is a problem, and rebound headache often occurs when doses are tapered. In patients with impending visual loss or incapacitating symptoms, placement of a ventricular shunt or optic nerve sheath fenestration may be indicated.[96]

Lumbar puncture is commonly performed to alleviate acute symptoms. Anecdotal reports indicate that this procedure alleviates headache, visual disturbances, and tinnitus for prolonged periods. It is unclear if a lumbar puncture can obviate the need for optic nerve sheath fenestration or CSF diversion. It is unclear how much CSF should be removed during the lumbar puncture. A reasonable goal is to remove sufficient CSF so that pressure is normalized.

Post-traumatic Headache

Headache is the most common symptom after minor head injury. It often is part of a complex syndrome that can include dizziness, fatigue, insomnia, irritability, memory loss, and difficulty with concentration. There are approximately 2 million closed head injuries per year, and post-traumatic headache (PTHA) occurs in an estimated 30 to 50% of patients with these injuries.[98] Acute PTHA develops hours to days after the injury and resolves within 3 to 6 months.[99] Chronic PTHA may last several months to years and may mimic other forms of headache, including tension and migraine headaches. The presence of headache, dizziness, or nausea on initial presentation is strongly associated with the development of chronic PTHA.[100]

Patients in whom PTHA develops after minor head injuries have normal findings on neurologic examination and neuroimaging studies. The pathophysiologic mechanism for their symptoms is unclear and may have both anatomic and functional components. Most patients are concerned about the cause of the headache more than about the headache itself.

Treatment is symptomatic. For acute PTHA, analgesics such as acetaminophen or NSAIDs are adequate for pain control. For chronic PTHA, treatment should be individualized by the type of headache and associated symptoms the patient is experiencing. Antidepressants and beta-blockers may be effective in selected patients.

Acute Glaucoma

Patients with acute angle closure glaucoma present with sudden onset of severe pain localized to the affected eye that may radiate to the ear, sinuses, teeth, or forehead. Visual symptoms, including blurriness, halos around lights, and scotomas, typically are present, and many patients also experience nausea and vomiting. The underlying pathophysiologic mechanism is congenital narrowing of the anterior chamber angle that under certain conditions closes, resulting in a significant rise in intraocular pressure. Episodes can

www.ketabpezeshki.com 66485457-66963820

be precipitated by entering a low-light environment such as a movie theater, with resultant pupillary dilation, or by the use of medications such as mydriatics (e.g., for dilated ocular examination), sympathomimetics (e.g., pseudoephedrine), or agents with anticholinergic properties (e.g., antiemetics, antihistamines, antipsychotics, antidepressants).

Physical examination reveals a red eye with a fixed, mid-dilated pupil, corneal clouding, and shallow anterior chamber. The diagnosis is confirmed by demonstration of markedly elevated intraocular pressure in the range of 60 to 90 mm Hg (normal is less than 21 mm Hg).

Treatment includes topical miotics, topical beta-blockers, oral carbonic anhydrase inhibitors (e.g., acetazolamide, 250 mg four times daily), intravenous osmotic agents (e.g., mannitol), and prompt referral to an ophthalmologist. The potential for diagnostic confusion between acute glaucoma, iritis, and cluster headache should be recognized. Although cluster headache may arise with pain, nausea, and a red eye, vision is not affected and the pupil generally is small and the eyelid is ptotic (from an oculosympathetic paresis). Acute iritis also arises with a painful red eye, but only acute angle closure glaucoma is associated with markedly elevated intraocular pressure.[101,102]

Post–Dural Puncture Headache

Principles of Disease and Pathophysiology

Headache is the most common complication of lumbar puncture, occurring in up to 40% of patients.[103] The incidence is highest in the 18- to 30-year age group, but this complication is uncommon in young children and in adults older than 60 years. Although the onset often is immediate, patients may not report symptoms for several days. In a majority of affected persons, the duration of headache is less than 5 days.[103]

The cause of post–dural puncture headache (PDPH) is not entirely clear. The most likely explanation is a persistent CSF leak that exceeds CSF production, resulting in CSF hypotension. If sufficient CSF is lost, the brain descends in the cranial vault when the patient assumes the upright position, leading to increased traction on the pain fibers. Thus the headache is characteristically positional and increases with the upright position and decreases with recumbency. The amount of time a patient remains recumbent after lumbar puncture does not appear to affect the incidence of headache.[104]

Certain factors have been implicated as causes of PDPH, including the size or diameter of the spinal needle, the orientation of the bevel during the procedure, and the amount of fluid withdrawn. Smaller-diameter needles cause less leakage, and it is postulated that insertion of the needle with the bevel up (i.e., bevel pointing up when the patient is in the lateral position) minimizes damage to the dural fibers. Use of atraumatic needles or pencil-point needles (e.g., Whitaker or Sprotte) also has been shown to reduce the incidence of PDPH significantly.[105,106]

Clinical Features

PDPH typically is bilateral, throbbing, and exacerbated by the upright position. Associated signs and symptoms include neck stiffness, nausea, vomiting, auditory disturbances including tinnitus and hearing loss (hypoacusis), and ocular symptoms including blurred vision and diplopia.[103]

Treatment

Most PDPHs resolve spontaneously within a few days with bed rest, adequate hydration, and mild analgesics. For persistent headaches, methylxanthine agents may be useful. Caffeine sodium benzoate (500 mg in 1 L of fluid) may be effective.[107] For severe headaches lasting longer than 24 hours, an epidural blood patch (autologous blood clot) relieves the headache in the majority of patients.[108]

Intracranial Infection

Headache is common among patients with intracranial infections, including meningitis, brain abscess, encephalitis, and acquired immunodeficiency syndrome. The severity and type of headache vary by the specific infection.

With acute bacterial meningitis, the patient often has a severe bursting headache that rapidly increases in severity during a short period. These patients typically have significant meningismus, with both Kernig's and Brudzinski's signs. With viral meningitis, patients also may complain of severe headache and nuchal rigidity, but the course is more indolent than with bacterial meningitis.[109]

The severity of headache associated with encephalitis depends on the type of virus involved. For example, the headache is usually mild with mumps encephalitis. With herpes simplex infection, however, the headache is abrupt and severe and frequently is associated with confusion, fever, altered level of consciousness, seizures, and focal neurologic signs. Patients with brain abscess often have headache as their presenting complaint. As the infection progresses, vomiting, focal neurologic signs, and depressed level of consciousness typically develop.[110]

Headache is a frequent complaint in patients with human immunodeficiency virus infection and can be caused by a number of conditions, including aseptic meningitis, toxoplasmosis, cryptococcal or tuberculous meningitis, and cytomegalovirus encephalitis. Cryptococcal meningitis in particular can be indolent but eventually lethal. Because spinal fluid analysis may be relatively bland, clinicians need to maintain a high index of suspicion for this particular pathogen as T-cell counts dwindle.[111]

In a majority of cerebral infections, the mechanism of head pain includes meningeal irritation and increased ICP. In addition, headache may be a general reaction to fever or the toxic products of the infecting agent.[110]

Hypertensive Headache

Contrary to common belief, hypertension is not an important cause of headache, and the occurrence of headache and hypertension in the same patient is often coincidental. Whether some patients with mild to moderate hypertension suffer from headache caused by elevated blood pressure is uncertain. The rate of blood pressure increase is more important as a cause of headache than the absolute blood pressure value is. Diastolic pressures lower than 130 mm Hg are rarely the cause of headache.[2]

Nonetheless, the association of headache with severe hypertension is well documented. Acute, severe headache is a prominent symptom of hypertensive encephalopathy, and most patients have blood pressure readings in the range of 250/150 mm Hg. Other conditions include headache secondary to toxic agents (e.g., drug-induced hypertension), pheochromocytoma, and eclampsia.[2]

The headache of severe hypertension typically is diffuse and is worse when the patient awakes in the morning and gradually subsides during the course of the day. Treatment is directed at lowering of the blood pressure; in most cases, the headache is relieved within 24 hours. In patients with hypertensive encephalopathy, the headache may persist for days until brain edema has resolved.

www.ketabpezeshki.com 66485457-66963820

Cervicogenic Headache

Cervicogenic headache refers to headache originating from disorders of the neck. Diagnosis is based on the presence of one of the following three distinct sets of symptoms[112]:

1. Unilateral headache triggered by movements of the head or neck or certain head positions
2. Unilateral headache triggered by pressure on the neck
3. Unilateral headache spreading to the neck or possibly the ipsilateral shoulder or arm

Many of these headaches are reported after a whiplash injury. Even though neck structures play a primary role in the pathophysiologic process of some headaches, clinical patterns indicating a neck-headache relationship have not been adequately defined.

Medication-Overuse Headache

Excessive analgesic or antimigraine medication use and withdrawal from these medications can worsen an existing headache disorder in susceptible patients. Medication-overuse headache is underdiagnosed and often difficult to manage. It occurs in patients with a primary headache disorder (e.g., migraine, tension type) who use immediate-relief medications on a near-daily basis, often in excessive quantities. Medications that have been implicated include NSAIDs, aspirin or acetylsalicylic acid, acetaminophen, barbiturate-analgesic combinations, opioids, caffeine, ergotamine, and triptans. Often, patients with this disorder describe preemptive use of drugs, in anticipation of—rather than for—headache. Women are affected more commonly than men are, and the most frequently affected age group is that of persons between 30 and 40 years. The headache itself is variable and may be accompanied by asthenia, nausea, anxiety, depression, and difficulty with concentration. Typically, it is worse on awakening in the morning and after physical exertion.[113]

The symptomatic medication that leads to the development of this disorder initially provides some pain relief to the patient, but tolerance develops over time, and larger doses are required to obtain symptomatic improvement.

Treatment requires complete withdrawal of the medication being overused while preventive therapy is initiated and a new acute headache therapeutic. In addition, these patients require a comprehensive education and follow-up program with pharmacologic, dietary, and behavioral components.[113]

High-Altitude Headache

Headache is one of the cardinal manifestations of acute mountain sickness and can occur at altitudes higher than 5000 feet above sea level in unacclimatized persons. The headache is throbbing in nature, located in the temporal or occipital areas, and probably caused by a mild increase in ICP secondary to brain swelling.[114] It is worse at night or in the early morning and exacerbated by the Valsalva maneuver or bending forward.[115] Other findings associated with high-altitude illness include fatigue, nausea, vomiting, dizziness, insomnia, and altered mental status. Pulmonary edema and cerebral edema develop in severe cases. The treatment of these conditions includes supplemental oxygen and descent to a lower altitude.

Reversible Cranial Vasoconstriction Syndrome

Reversible cranial vasoconstriction syndrome (RCVS) is a disorder of cerebral arteries characterized by segmental areas of vasoconstriction. It causes recurrent thunderclap headache in susceptible patients and is a cause of ischemic or hemorrhagic stroke. The headache is often described as severe and throbbing and is associated with nausea, vomiting, and photophobia. The headache may be provoked by use of vasoactive medications or substances. RCVS has been called by the eponym Call-Fleming syndrome and is the same disease as postpartum angiopathy or migrainous vasospasm. Typically, patients present with a thunderclap headache with neurologic deficits or seizures, and during cerebral vascular imaging, abnormal areas of vasoconstriction, described as sausage on a string, are noted. Repeated vascular imaging within 3 months shows resolution of the areas of vasoconstriction. Treatment with calcium channel blockers has been described, although when to initiate treatment is not clear. The prevalence of this presumably rare disorder is not known. However, many patients who present to an ED with a thunderclap headache cannot be assigned a specific diagnosis. It is possible that the prevalence of this disorder is greater than currently understood.[116,117]

OTHER HEADACHE DISORDERS AND FACIAL PAIN

Nummular Headache

Relatively recently described, nummular headache is a highly localized headache, rarely more than moderately painful, that is felt exclusively in a rounded, 2- to 6-cm area of the head. Epidemiology and pathogenesis are not yet well understood. Nummular headache is usually responsive to nonsteroidals, although a high frequency of headaches may be prevented with tricyclic antidepressants. In patients with new onset of headache, underlying disease of the scalp or dura should be excluded.[118]

Trigeminal Neuralgia

Trigeminal neuralgia is a painful unilateral affliction of the face characterized by brief electric shock–like (lancinating) pains limited to the distribution of one or more divisions of the trigeminal nerve. Pain is commonly evoked by trivial stimuli (e.g., washing, shaving, smoking, talking, or brushing teeth) but also may occur spontaneously. Individual attacks are brief, lasting a few seconds to less than 2 minutes, and are stereotypic in the individual patient. The lightning-like pains and unilateral grimaces characteristic of trigeminal neuralgia led to the designation *tic douloureux*. The diagnosis is straightforward in most patients on the basis of clinical criteria. However, because these symptoms also can be caused by an underlying mass lesion or multiple sclerosis, MRI is indicated in previously undiagnosed patients and when sensory loss or motor dysfunction is present.[119]

Several oral drugs have been effective in treatment of trigeminal neuralgia, including carbamazepine and oxcarbazepine. Phenytoin and baclofen may also be useful. However, approximately 30% of patients fail to respond to medical therapy. In these patients, surgical management, by alcohol or glycerol injection or microvascular decompression, may be indicated. For patients with acute severe pain, parenteral treatment with an antiepileptic drug such as phosphenytoin may be useful.[120]

Coital Headache

Coital cephalgia is a recurrent, benign headache associated with sexual activity and is more common in men than in women. Different types have been described, including headaches that occur before, during, or immediately after orgasm. They typically are

www.ketabpezeshki.com 66485457-66963820

occipital in location and may increase in severity with mounting sexual excitement. Their duration can be minutes to hours. On occasion, some patients experience a sudden, explosive headache that occurs during orgasm. In these patients, SAH should be ruled out.[121,122]

Cough and Exertional Headache

In some patients, severe headache can be provoked by rapid increase in intra-abdominal pressure, such as coughing, sneezing, laughing, heavy lifting or exertion, and Valsalva maneuver. The pain starts within a few seconds of the precipitant and typically is brief when it is associated with cough but can last as long as 24 hours when it is associated with exertion. The headache is bilateral and throbbing in nature and in a majority of patients resolves spontaneously without persistent neurologic symptoms (e.g., neck stiffness or photophobia). In some patients, the headache may be secondary to structural lesions, especially in the posterior fossa[113]; therefore, all previously undiagnosed patients require CT, or preferably MRI, followed by lumbar puncture to rule out intracranial disease, including SAH. For patients with recurrent benign exertional headache, treatment includes avoidance of the underlying triggering mechanism and use of analgesics as necessary. For patients with exertional headache, NSAIDs, including indomethacin, have been effective.[121,122]

KEY CONCEPTS

- Headache is a common presenting complaint in the ED. The goals of evaluation in this setting are (1) to distinguish between benign primary headache disorders and potentially life-threatening secondary causes of headache and (2) to treat the headache pain effectively, and rapidly, without causing undue side effects.
- A majority of patients do not have abnormal neurologic findings; therefore, the key to a successful diagnosis is a thorough and systematic history.
- Patients with the following headache presentations are at risk for serious underlying disease: sudden explosive headache; first or "worst-ever" headache; new-onset headache after the age of 50 years; headache associated with papilledema, alteration in or loss of consciousness, or focal neurologic symptoms; subacute headache with increasing frequency or severity; headache associated with fever, cancer, or immunosuppression; and headache triggered by exertion, sexual activity, or Valsalva maneuver.
- The need for diagnostic studies is dictated by the suspected secondary cause of headache.

Chapter 104

Delirium and Dementia

Jeffrey P. Smith and Jennifer Seirafi

PERSPECTIVE

Emergency physicians are frequently presented with patients exhibiting neurobehavioral abnormalities. These can be a harbinger of a serious medical condition, and critical decisions must be made expeditiously about diagnostic evaluation, therapeutic intervention, and disposition. The first critical action is to recognize the presence of the neurobehavioral abnormality. The second is to distinguish delirium from dementia or some other neuropsychiatric condition.

In the past, terms such as acute confusional state, sundowning, and organic brain syndrome have been used to describe a host of abnormal cognitive states that can be observed in the emergency setting. These terms have loosely defined a group of neurobehavioral disorders that are caused by a physiologic disturbance. Organic brain syndrome is a nebulous term that the *Diagnostic and Statistical Manual of Mental Disorders* (fourth edition, text revision) eschews because the "organic" connotation implies that so-called functional mental disorders are without a biologic basis.[1]

Several key features best distinguish delirium from dementia: the time course of disease evolution, the presence of autonomic system involvement, the level of consciousness, and the presence of an underlying disease processes. Delirium is characterized by a fluctuating level of neurobehavioral disturbance typically progressing during minutes to hours to days. Delirium is a direct consequence of an acute systemic or central nervous system (CNS) stressor. Dementia, on the other hand, tends to follow a more gradual course, with evolution during months to years. Although patients with dementia exhibit confusion, disturbance in level of consciousness usually is not a feature, and manifestations of autonomic nervous system abnormalities are minimal or absent.

The evaluation of patients who present to the emergency department (ED) with a disturbance of neurobehavioral state is best conducted in accordance with the following basic guidelines:

1. The first step is to determine whether this state represents delirium or dementia. The clinical findings may be subtle, and establishment of the diagnosis can be challenging, especially because delirium may be superimposed on dementia and dementia remains an independent risk factor for delirium.[2,3] Early symptoms and signs may go unrecognized unless an adequate history is obtained from the patient, family members, and caregivers. A careful examination must include memory and cognitive assessment with a mental status screening examination.
2. Supportive care must be provided. This care may range in extent from aggressive airway and cardiovascular support to pharmacologic or physical restraint to simply placing the patient in a quiet room with appropriate environmental support.
3. A diligent search must be initiated for the underlying precipitating stressors in patients presenting with delirium.

DELIRIUM

Definition and Background

Delirium is a syndrome that can be defined as an acute or subacute state of cognitive dysfunction caused by an underlying physiologic condition. Terms that have been used interchangeably with delirium include acute organic brain syndrome, acute confusional state, reversible cerebral dysfunction, metabolic encephalopathy, toxic encephalopathy, and febrile delirium. The word *delirium* is derived from the Latin *delirare,* which literally means "to go out of the furrow" (in a more modern sense, "to derail"), but it is used figuratively to mean "crazy" or "deranged."

Several key features are necessary for a diagnosis of delirium (Box 104-1). Patients with delirium have disturbances in consciousness, memory, cognition, and perception. These disturbances tend to develop during a short time (hours to days). The disturbance in consciousness may be manifested initially as an inability to focus attention. The fluctuating course of symptoms and inattention are the hallmarks of delirium. Deficiencies in cognition may be manifested by disorientation and memory deficits. Perceptual disturbances include hallucinations and delusions. The delirious patient may be somnolent or agitated, and the thought process may range from mildly disturbed to grossly disorganized. The clinical presentation may be subdued or explosive. The patient's sleep-wake cycle may be altered or reversed; agitation often is present during the night. Historically, delirium referred to a hyperactive state marked by agitation and emotional lability (e.g., delirium tremens). An important point, however, is that delirium has several psychomotor subtypes: hyperactive (mania), hypoactive (depressed), and mixed type.[4]

The exact incidence of delirium in the overall ED population is unknown. However, the prevalence of delirium among elders who present to the ED is approximately 10 to 20%.[5] Geriatric patients are at particularly high risk for the development of delirium. Advanced age, dementia, and underlying medical illness are strongly associated with delirium. Multiple medications, drugs, and alcohol also are associated with delirium.[6] Severe psychological stress and sleep deprivation may facilitate the development of delirium.

Box 104-1 Diagnostic Criteria for Delirium

Four Key Characteristics
- Clouding of consciousness with reduced ability to focus, sustain, or shift attention
- A cognitive change (e.g., memory deficit, disorientation, language disturbance) or perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia
- Development of the disturbance during hours to days, with a tendency to fluctuate in the course of the day
- Evidence from the history, physical examination, or laboratory studies that the disturbance is caused by a general medical condition, medication or other substance exposure, substance withdrawal, or multiple etiologic disorders

Additional features may include psychomotor behavioral disturbances such as hypoactivity, hyperactivity with increased sympathetic activity, and emotional lability.

Modified from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

Table 104-1 Causes of Delirium: "I Watch Death" Mnemonic

CAUSE	FORM
Infectious	Sepsis, encephalitis, meningitis, syphilis, central nervous system abscess
Withdrawal	Alcohol, barbiturates, sedative-hypnotics
Acute metabolic	Acidosis, electrolyte disturbance, hepatic or renal failure, other metabolic disturbances (↑ or ↓ glucose, magnesium, calcium)
Trauma	Head trauma, burns
CNS disease	Hemorrhage, stroke, vasculitis, seizures, tumor
Hypoxia	Acute hypoxia, chronic lung disease, hypotension
Deficiencies	Vitamin B_{12}, hypovitaminosis, niacin, thiamine
Environmental	Hypothermia, hyperthermia, endocrinopathies (diabetes, adrenal, thyroid)
Acute vascular	Hypertensive emergency, subarachnoid hemorrhage, sagittal vein thrombosis
Toxins or drugs	Medications, street drugs, alcohol, pesticides, industrial poisons (e.g., carbon monoxide, cyanide, solvents)
Heavy metals	Lead, mercury

Modified from Wise MG: Delirium: Differential diagnosis for delirium: Critical items (I WATCH DEATH). In: Yudofsky SC, Hales RE (eds): The American Psychiatric Press Textbook of Neuropsychiatry, 2nd ed. Washington, DC, American Psychiatric Publishing, 1992.

Pathophysiology

At a cellular level, delirium is the result of widespread alteration in cerebral metabolic activity, with secondary deregulation of neurotransmitter synthesis and metabolism. Both the cerebral cortex and the subcortical structures are affected, producing changes in arousal, alertness, attention, information processing, and the normal sleep-wake cycle.

Although the exact pathophysiologic process is not well understood, multiple neurotransmitters have been implicated in causing delirium. One theory is that delirium is associated with a derangement of central cholinergic transmission. Serum anticholinergic activity is increased, and low levels of acetylcholine are seen in older patients with delirium.[7] Increased serotonin levels have been found in hepatic encephalopathy, serotonin syndrome, sepsis, and psychedelic drug ingestion.[8] Some of the disturbances that occur in delirium are deficiencies of substrates for oxidative metabolism (e.g., glucose, oxygen); disturbances of ionic passage through excitable membranes; increase in cytokines; imbalance of normal noradrenergic, serotoninergic, dopaminergic, and cholinergic homeostasis; and, in some cases, synthesis of false neurotransmitters.[9] Drugs and exogenous toxins can produce delirium through direct effects on the CNS. Although the limbic system appears to be particularly vulnerable to the effects of these drugs, the cerebral hemispheres and the brainstem also can be profoundly affected.

Tricyclic antidepressants can cause delirium by cholinergic inhibition; sedative-hypnotics depress activity in the CNS, especially in the limbic system, thalamus, and hypothalamus. Narcotics affect CNS activity primarily by interacting with various opioid receptor sites. Depending on the opioid receptor type affected, the physiologic response may be analgesia, euphoria, sedation, dysphoria, delusions, or hallucinations. Psychedelic drugs probably act as agonists at serotonin receptor sites. Phencyclidine (PCP) inhibits reuptake of dopamine, norepinephrine, serotonin, and α-aminobutyric acid and also may act as a false neurotransmitter.

Hyperthermia and hypothermia can cause delirium, probably as a result of changes in the cerebral metabolic rate. In hypothermia, cerebral metabolism decreases 6 to 7% for each 1° C decrease in temperature from 35 to 25° C. In hyperthermia, cellular damage with uncoupling of oxidative phosphorylation begins to occur at temperatures higher than 42° C. Patients suffering from heatstroke may have cerebral edema, degenerative neuronal changes (especially involving Purkinje cells of the cerebellum), and petechiae in the walls of the third and fourth ventricles. Delirium occurring at temperatures below 40° C is multifactorial in origin and not caused solely by increased core temperature.

Delirium caused by metabolic abnormalities, such as hyponatremia, hypernatremia, hyperosmolarity, hypercapnia, and hyperglycemic disorders, is associated with a variety of metabolic disturbances at the neuronal and astrocyte levels. Such disturbances may include impairments in energy supplies, changes in resting membrane potentials, changes in cellular morphology, and changes in the brain water volume.

Most patients with delirium have reduced cerebral metabolic activity. This reduction in cerebral metabolism is reflected by a decrease in the frequency of background electrical activity on the electroencephalogram (EEG). Exceptions are hyperthermia, sedative-hypnotic withdrawal, delirium tremens, and certain drug-induced states, in which the cerebral metabolism is either normal or increased.

Etiology

The causes of delirium are legion (Table 104-1). Within the geriatric population, medications are a common cause of delirium, whereas drugs (including ethanol) are the most common cause of delirium in the younger adult population. Acute cognitive dysfunction may be secondary to drug overdose, withdrawal syndromes, and adverse or idiosyncratic reactions.

The list of commonly prescribed drugs causing delirium is extensive and includes antibiotics (antifungal, antimalarial, and antiviral agents; numerous antibacterial agents, including the quinolones and macrolides), anticholinergic drugs (antihistamines, antispasmodics, muscle relaxants, tricyclic antidepressants), anticonvulsants, anti-inflammatory agents (corticosteroids, salicylates, and other nonsteroidal anti-inflammatory drugs), various cardiovascular medications (beta-blockers, antidysrhythmics, antihypertensives, cardiac glycosides), sympathomimetics (phenylpropanolamine), sedative-hypnotics, narcotics (transdermal

www.ketabpezeshki.com 66485457-66963820

fentanyl [Duragesic], morphine sulfate [Roxanol], hydromorphone HCl [Dilaudid], oxycodone HCl [OxyContin]), miscellaneous drugs (aminophylline, cimetidine, lithium, chlorpropamide), over-the-counter medications with anticholinergic properties, and caffeine-containing products.[6]

Many "street drugs" with significant abuse potential, such as hallucinogens, amphetamines, PCP, cocaine, and methylenedioxymethamphetamine (MDMA, ecstasy), can cause delirium, as can intoxication with any of the alcohols (e.g., ethanol, methanol, ethylene glycol).

Exposure to industrial chemicals (e.g., carbon disulfide, heavy metals, insecticides, cyanide, carbon monoxide) can cause a wide range of symptoms that include acute delirium. In addition, ingestion of certain plants (e.g., nutmeg, foxglove, jimsonweed, psilocybin-containing mushrooms) can cause delirium.

Delirium can be one of the protean manifestations of a metabolic or nutritional abnormality. The most common metabolic disorder causing acute cognitive changes is diabetes mellitus. Hypoglycemia is the most common and readily reversible cause of acute confusion in the diabetic patient. Other causes of acute cognitive impairment in the diabetic patient are hyperglycemia, hyperosmolarity, and acid-base abnormalities. Severe metabolic abnormalities, including electrolyte disturbances, hypoxemia, hepatic insufficiency, renal insufficiency, and dysfunction of various endocrine glands (hyperthyroidism, hypothyroidism, Cushing's syndrome, hyperparathyroidism, and other endocrine disorders), can cause delirium. Deficiency of niacin, pyridoxine, folic acid, or vitamin B_{12} may be associated with an acute confusional state.

Delirium can be a prominent feature of any systemic infection, particularly in the very young, elders, and immunocompromised patients. Infectious and host factors together determine the degree of cognitive impairment. Extracranial infections that are associated with delirium include sepsis (particularly gram-negative sepsis), subacute bacterial endocarditis, Legionnaires' disease, Rocky Mountain spotted fever, malaria, typhoid fever, toxic shock syndrome, and several viral infections including influenza. Patients with CNS infections, including meningitis, encephalitis, and intracerebral abscess, may have acute cognitive dysfunction.

Another less common cause of delirium is CNS infarction in the distribution of the nondominant middle cerebral artery and the posterior cerebral artery. In patients who have a collagen vascular disease with CNS vasculitis, neuropsychiatric manifestations, including acute delirium, may be prominent. Paraneoplastic syndromes may include encephalopathy, with symptoms of confusion, catatonia, and dementia.

Patients who are immunocompromised may have multiple and unusual causes of acute delirium. Patients with immunosuppression secondary to malignant disease, drugs, or human immunodeficiency virus type 1 (HIV-1) infection may have acute brain dysfunction secondary to infection, complications of drug therapy, or the underlying disease itself.

Acute confusional states have been reported to be a more common herald of the onset of physical illness in the elderly than are fever, pain, and tachycardia.[2,3,10] Factors that predispose elders to delirium include the effects of aging on the brain, reduced capacity for homeostatic regulation, impaired vision and hearing, and age-related changes in the pharmacokinetics and pharmacodynamics of drugs.[11] The etiology of delirium in elders is usually multifactorial.

Clinical Features

The clinical manifestations of delirium are as variable as the causes. The clinical presentation can be so subtle as to go unrecognized or may be dramatic enough to disrupt the entire ED. The natural history of a patient's delirium can progress from apathy to marked agitation in the course of hours (see Box 104-1). Nonspecific prodromal symptoms such as anxiety, restlessness, and insomnia typically emerge during hours to days.

Key aspects of cognitive impairment should become evident during a careful history and examination. Disturbance in attention is central to the diagnosis of delirium. The patient is easily distractible and has difficulty remaining focused on a particular topic or interacting with a single person. Disorientation often accompanies the deficit inattention but is not an invariable feature. The patient usually is disoriented with respect to time and occasionally to place; in extreme cases, disorientation to person also may be noted. Delirium, however, may be present in a patient who is completely oriented to person, place, and time. A mental status examination that consists solely of questions that assess orientation will not detect delirium in these instances.

The patient with delirium always has some degree of memory impairment, with the greatest impact on short-term memory. Thought processes and speech may be disorganized. Disturbance in the sleep-wake cycle often occurs early in the course of delirium. Perceptual disturbances, including misperception of the environment, poorly formed delusions, and hallucinations, are common. The delirious patient may experience visual, auditory, tactile, gustatory, or olfactory hallucinations, in contrast to patients with acute functional psychosis, who typically experience only auditory hallucinations. In addition, the delirious patient has a reduced capacity to modulate fine emotional expression and may demonstrate extreme emotional lability.

The cognitively impaired patient may provide an unreliable history. Valuable information often can be obtained from family, friends, and out-of-hospital personnel. Specific inquiry should be made about the patient's current medical problems and previous medical history, including diabetes, hypertension, kidney or liver disease, and any neurologic or psychiatric problems. It is important to determine whether the patient is immunosuppressed or has risk factors for immunosuppression. A detailed medication history, including the use of prescribed and over-the-counter medications, dietary supplements, and alcohol or other substances, is essential. Out-of-hospital personnel should be able to provide information about the home environment, medication bottles belonging to the patient or found near the patient, and the possibility of trauma.

The physical examination should begin with a careful assessment of vital signs including pulse oximetry and a pain assessment. The delirious patient often exhibits abnormalities on such evaluation, including elevated or decreased pulse, blood pressure, respiratory rate, and temperature. The examination includes assessment of the head for signs of trauma and the pupils for symmetry of light reflex; funduscopic examination for hemorrhage or papilledema; examination of the ears for hemotympanum; evaluation of the neck for nuchal rigidity, bruits, and thyroid enlargement; assessment of the heart and lungs; evaluation of the abdomen for organomegaly and ascites; and examination of the extremities for cyanosis. The skin should be carefully examined for rashes, petechiae, ecchymosis, splinter hemorrhages, and needle tracks. The neurologic examination includes assessment of the cranial nerves, motor strength, sensation, and presence of abnormal movements (e.g., tremor, asterixis, myoclonus). The reflexes are assessed for symmetry and presence of hyperreflexia or hyporeflexia. Findings that typically suggest either a metabolic or a structural neurologic problem are not necessarily specific for that category of disorder. For example, asterixis is a hallmark of metabolic encephalopathy but can be seen in focal brain disease. Likewise, focal neurologic signs that typically are associated with structural CNS lesions also can be present in various metabolic abnormalities, such as hypoglycemia, hyperglycemia, hepatic encephalopathy, uremia, and hypercalcemia.

www.ketabpezeshki.com 66485457-66963820

The physical examination is not often helpful in determining the specific drug or class of drugs causing acute cognitive impairment. The one exception to this rule is toxidromes, which are constellations of signs and symptoms characteristic of intoxication with certain drugs or classes of drugs (see Chapter 147).

A brief mental status examination should be performed in all patients thought to have acute brain dysfunction. Although the concept is rather obvious, few physicians proceed beyond questions about the patient's orientation to person, place, and time when assessing mental status. Failure to diagnose subtle forms of delirium when they are present is directly related to omission of mental status testing.[12]

Several standardized tools for assessment of mental status have been successfully applied in the ED.[12-14] Mental status testing includes assessment of orientation, memory, attention, and concentration; several tests also incorporate assessments of constructional tasks, spatial discrimination, arithmetic ability, and writing. Cognitive functioning can be rapidly assessed in approximately 7 to 10 minutes. Memory assessment requires testing of the patient's ability to repeat short series of words or numbers (immediate recall), to learn new information (short-term memory), and to retrieve previously stored information (long-term memory). Constructional apraxia is assessed by having the patient perform tasks such as drawing interlocking geometric figures or clock faces and connecting dots. Dysnomia (inability to name objects correctly) and dysgraphia (impaired writing ability) are two of the most sensitive indicators of delirium. Almost all acutely confused patients exhibit writing impairments, including spatial disorganization, misspelling, and tremor.[13,15]

No single bedside cognitive test that can be administered quickly is ideal. The Mini-Mental State Examination (MMSE) developed by Folstein and colleagues has been validated more than any other test and most frequently is recommended as a rapid screening tool.[10,13,15,16] For hospitalized patients, this test has a sensitivity of 87% and a specificity of 82% for detection of organic brain syndrome. Some investigators report slightly better results when the test is modified and age is added as a variable in the analysis.[16] The MMSE does not measure executive function and is insensitive for detection of early signs of mild cognitive impairment (without dementia) or early dementia.[17]

The MMSE consists of a short series of questions that test orientation, registration (memory), attention, calculation, recall, and language (Fig. 104-1). The time for the test to be administered can be reduced to 5 minutes by elimination of the writing and drawing components with only a modest reduction in sensitivity. The registration section tests both immediate and short-term memory; the recall section also assesses short-term memory. The ability to recall two of three objects has 81% sensitivity and 74% specificity for exclusion of organic brain syndrome. Asking the patient to subtract "serial sevens" backward from 100 assesses attention, concentration, and arithmetic ability. This test is specific but not sensitive for absence of an organic brain syndrome; up to 40% of nondelirious, nondemented people fail to perform the tasks of this test correctly, reflecting limitations due to language ability and education. A total score of 23 or less is considered markedly abnormal and indicates an organic brain syndrome. As a general rule, patients with mild cognitive impairment have a score of 18 to 26 of 30, those with moderate impairment have a score of 10 to 18, and those with severe impairment have a score of less than 10.

The Quick Confusion Scale represents another attempt to quantify the attention aspects of mental status (see Chapter 17, Fig. 17-2). It has significant correlation with the MMSE, can be administered more quickly, and does not require constructional tasks.[18] Another useful diagnostic tool is the Confusion Assessment Method; it has a sensitivity of 93 to 100% and specificity of 90 to 95%.[19] This simple tool has four key features used for screening of delirium: acute onset and fluctuating course, inattention, disorganized thinking, and altered level of consciousness. For a definitive diagnosis of delirium, the first two features and one of the last two must be present. It has proved to be a valuable tool because of its ease and interobserver reliability. In addition, it has been shown to be more sensitive than clinical impression alone.[18,20] The Six-Item Screener is another brief test of cognition that was found to be 94% sensitive and 86% specific in identifying disturbance of cognition in older patients.[15]

All bedside tests of cognition have limitations and can miss mild degrees of impairment. The patient's level of education and general intelligence can substantially affect the outcome. Furthermore, a single bedside test reflects a patient's cognitive functioning at only one point in time. For a diagnosis of delirium (or dementia) to be established, an essential criterion is a documented decline from the patient's baseline level of cognitive functioning,

Maximum Score	Orientation
5	What is the (year)(season)(date)(day)(month)?
5	Where are we (city)(state)(country)(hospital)(floor)?
	Registration
3	Name three objects: one second to say each. Ask the patient for all three after you have said them. Give one point for each correct answer. Repeat them until all three are learned. Count trials and record number.
	Attention and calculation
5	Serial sevens backwards from 100 (stop after five answers). Alternatively, spell WORLD backward.
	Recall
3	Ask for the three objects repeated above. Give one point for each correct answer.
	Language and praxis
2	Show a pencil and watch, and ask subject to name them.
1	Ask the patient to repeat the following: "no ifs, ands, or buts."
3	Three-stage command: "Take this paper in your right hand, fold it in half, and put it on the floor."
1	Read and obey the following: "Close your eyes." (Written on a piece of paper.)
1	Write a sentence. (Must contain a noun and a verb and be sensible. Ignore grammar and punctuation.)
1	Copy this design (interlocking pentagons). Must contain all angles and two must intersect.

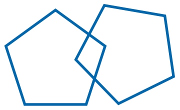

Figure 104-1. Mini-Mental State Examination. (Adapted from Folstein MF, Folstein SE, McHugh PR: "Mini-mental state": A practical method for grading the cognitive state of patients for the clinician. J Psychiatr Res 12:189, 1975.)

www.ketabpezeshki.com 66485457-66963820

and the sensitivity of these tests increases when they are repeated over time.

Diagnostic Evaluation and Ancillary Studies

Some reversible causes of delirium can be diagnosed by a number of basic, readily available tests. The following laboratory tests can be helpful in evaluation of the delirious patient: a complete blood count (CBC; hemoglobin, leukocyte count with differential, platelet count, and mean corpuscle volume), serum electrolyte values, glucose concentration, calcium concentration, and urinalysis. The CBC may suggest unusual but potentially treatable abnormalities, such as thrombotic thrombocytopenic purpura, megaloblastic anemia, hyperviscosity from myelogenous leukemia, and unsuspected infection. The anion gap should be determined in all patients with altered mental status. An elevated anion gap (>15 mEq/L) may indicate the presence of unmeasured anions, such as sulfate in renal failure; keto acids in diabetic or alcoholic ketoacidosis; lactate in postictal states or associated with hypotension; and exogenous toxins, such as ethylene glycol, methanol, and salicylates. A pulse oximetry measurement should be obtained in all patients to screen for hypoxemia, and an arterial blood gas analysis is warranted in those patients at risk for respiratory failure with carbon dioxide retention. Suspected occult infection warrants urinalysis and chest radiography. In elders, an electrocardiogram should be obtained to exclude a silent acute coronary syndrome. Ammonia level should be considered in patients with cirrhosis, ascites, or asterixis. Despite these diagnostic evaluations, no cause is found for delirium in up to 16% of patients.[6]

Toxicology screens are overused as diagnostic tests and have limited usefulness in the evaluation of most patients with delirium. Additional laboratory studies outside the scope of the ED evaluation that may be appropriate when the cause of delirium remains unknown include thyroid function studies, vitamin B_{12} and folic acid assays, rapid plasma reagin test, measurement of serum antinuclear antibodies, urinary porphobilinogen assay, and screens for heavy metals.

Patients with a history of trauma (especially those taking anticoagulant medications), previous neurosurgical procedures, immunodeficiency, or focal neurologic signs require a head computed tomography (CT) scan to detect structural lesions causing delirium. Early infarctions, small brainstem lesions, meningitis or encephalitis, closed head injuries, sagittal vein thrombosis, and small isodense subdural hematomas may be missed on a CT scan. In addition, approximately 2 to 8% of acute subarachnoid hemorrhages are not detected by head CT scan and require lumbar puncture for diagnosis. The role of magnetic resonance imaging (MRI) in the evaluation of the delirious patient has not been clearly established. MRI is superior to CT for detection of small intercerebral and brainstem lesions, small brain contusions, certain encephalitides, and abnormalities of white matter (e.g., leukoencephalopathy). MRI perfusion scans are more sensitive in detecting an acute vascular event.

Cerebrospinal fluid (CSF) analysis is an essential part of the evaluation in selected patients with delirium. In patients with fever and cognitive dysfunction, even without meningismus, a lumbar puncture should be performed to rule out meningitis. This test is particularly important in the very young, elders, and immunocompromised patients, who are less likely to show classic signs of meningitis. Patients with focal neurologic deficits, immunocompromised states, or evidence of increased intracranial pressure should undergo head CT before lumbar puncture, and they should receive antibiotics before the CT scan.

Although it is rarely practical in the ED setting, the EEG can be a valuable diagnostic tool in determining the presence of delirium. Bilateral diffuse symmetrical electroencephalographic abnormalities are a relatively consistent feature of delirium. In most cases, the changes consist of a nonspecific generalized slowing from the baseline activity and can be useful in distinguishing delirium from other neurobehavioral abnormalities.

Table 104-2 Comparison of Delirium and Acute Psychosis

CHARACTERISTIC	DELIRIUM	ACUTE PSYCHOSIS
Onset	Acute	Acute
Vital signs	Typically abnormal (fever, tachycardia)	Normal
Prior psychiatric history	Uncommon	Common
Course	Rapid, fluctuating	Stable
Psychomotor activity	Variable	Variable
Involuntary activity	Possible asterixis, tremor	Absent
Cognition function		
Orientation	Usually impaired	Occasionally impaired
Attention	Globally impaired	May be disorganized
Concentration	Globally impaired	Impaired
Hallucinations	Visual, visual and auditory	Primarily auditory
Delusions	Transient, poorly organized	Systematized
Speech	Pressured, slow, possibly incoherent	Usually coherent
Course	Typically resolves	Responds to therapy, recurrence common

Differential Diagnosis

Considerations in the differential diagnosis for apparent delirium include functional psychiatric disorders and dementia. Depression, mania, paranoia, and schizophrenia all may resemble delirium. Several clinical features are helpful in distinguishing between organic and functional syndromes (Table 104-2).

Dementia, like delirium, is characterized by global cognitive impairment. Unlike delirium, dementia tends to be an insidious process that develops during months to years with little fluctuation during hours or days. Typically, the patient's vital signs are normal. Dementia occurs primarily in the elderly. A point worthy of emphasis is that patients with dementia are five times more likely to develop delirium.[2,3,5,6]

Management

Delirium constitutes a medical emergency. The outcome depends on the cause of the delirium, the patient's overall health status, and the timeliness of treatment. The presence of hyperactive or hypoactive delirium has some prognostic significance.[2] The hypoactive form of delirium tends to be more common in elders and carries a worse overall prognosis, perhaps because it often goes unrecognized. Acute recognition and management of delirium in elders are essential because delirium in this population is associated with increased risk of long-term institutionalization, development of dementia, and increased overall mortality.[21]

Patients who present with acute delirium should be screened quickly for readily reversible causes, such as hypoglycemia, hypoxia, and narcotic overdose. Acute intoxication from a number of drugs or chemical agents, including tricyclic antidepressants, ethylene glycol, cholinesterase inhibitors, anticholinergic agents, carbon monoxide, and cyanide, requires prompt attention. Although supportive measures are the mainstay of treatment in

www.ketabpezeshki.com 66485457-66963820

most poisonings and intoxications, most of these toxins have specific antidotes.

Other conditions requiring immediate medical intervention include infections. Patients with signs of acute meningitis or sepsis should receive antibiotics within 30 minutes of arrival to the ED along with appropriate fluid resuscitation. Other emergent conditions that may be manifested with delirium and necessitate immediate intervention include severe hypothermia, hyperthermia, and CNS vascular conditions, including hypertensive encephalopathy, acute epidural or subdural hematoma, subarachnoid hemorrhage, and stroke. Patients with Wernicke's encephalopathy require immediate treatment with 100 mg of intravenous thiamine, with titration of additional doses until the ophthalmoplegia resolves. Resistance to thiamine may result from hypomagnesemia because magnesium is a cofactor for thiamine transketolase. Glucose administration in patients with severe thiamine deficiency may precipitate Wernicke's encephalopathy. The specific treatment of delirium tremens (and other alcohol withdrawal syndromes) involves the substitution of a long-acting drug that is cross-tolerant with the alcohol. Benzodiazepines are the agents of choice to induce sedation. Delirium secondary to dehydration, hyponatremia, hypernatremia, hypercalcemia, and hepatic or renal disease gradually resolves during hours to days with appropriate treatment.

Supportive care for all patients with delirium includes provision of an appropriate environment with adequate lighting, minimization of sensory overload, placement of the patient in an area that can be easily observed by staff, and use of stretcher side rails to prevent falls. Use of "sitters" may be necessary because patients may require constant supervision. It is important to protect the patient from self-harm or from injuring other patients or staff. In cases of hyperactive delirium, the patient may need to be initially restrained physically until pharmacologic control takes effect. Restraints should be viewed only as a temporizing action because they can increase agitation and the risk of injury to the patient. Physical restraints in agitated patients have been associated with significant injuries and even death by asphyxiation and are not a substitute for pharmacologic control.[22,23]

Pharmacologic restraint has become the cornerstone of behavioral management. Classes of drugs that have been used for management of delirium include the antipsychotics and benzodiazepines. The ideal sedating drug should have the following characteristics: low toxicity with minimal anticholinergic effects, ease of administration, short half-life, minimal effects on the cardiovascular and respiratory systems, and no effect on the seizure threshold. Antipsychotic medications used to treat delirium include the butyrophenones and the newer atypical antipsychotic agents.[24-29] Although no one drug is ideal, the butyrophenones, specifically haloperidol (Haldol), are considered the agents of choice for control of agitation in acute delirium on the basis of extensive clinical experience.[23,24] Increasing evidence indicates that compared with haloperidol, the newer atypical antipsychotic agents (risperidone, olanzapine, ziprasidone, aripiprazole) may have equal or better efficacy and fewer side effects (especially akathisia and dystonia) for management of acute agitation.[25-29] In addition, the atypical antipsychotic agents received a black box warning from the U.S. Food and Drug Administration (FDA) in 2005 for use in elderly demented patients with agitation because of the increased mortality noted in this special population of patients (although this is associated with long-term use).[30] Phenothiazines and droperidol, a butyrophenone pharmacologically similar to haloperidol, can cause orthostatic hypotension, lower the seizure threshold, and have anticholinergic effects, making them unacceptable for the treatment of delirium. The use of droperidol for management of agitation has been significantly curtailed since the FDA gave this drug a black box warning because of the association of droperidol use with QT prolongation and torsades de pointes; however, many clinicians think that the warning is unjustified.[31,32] The opioids morphine and meperidine (Demerol) are capable of inducing dysphoria and can exacerbate respiratory depression and hepatic encephalopathy and should not be used for behavior control in the agitated delirious patient.

Benzodiazepines are the drugs of choice for management of delirium caused by withdrawal from alcohol or sedative-hypnotics, for which a long duration of action is desirable. Lorazepam, a shorter-acting benzodiazepam that undergoes glucuronide conjugation with rapid renal clearance, is the preferred agent for treatment of withdrawal symptoms. In general, they are not indicated in the management of symptoms of delirium caused by other conditions.[33] Although limited data exist, the benzodiazepines may be helpful with ingestion of stimulants such as hallucinogens, cocaine, and PCP. The benzodiazepine diazepam (Valium) should be avoided as an agent for treatment of agitated behavior in most delirious patients because of its long half-life, respiratory depressant effect, and risk of drug accumulation with repeated dosing. Benzodiazepines can worsen confusion, and use of this class of drugs is an independent risk factor for delirium, especially in the elderly.[34,35]

As the primary drug for control of hyperactive delirium, haloperidol is a potent dopamine-blocking medication with virtually no anticholinergic and minimal hypotensive effects. The main effect of the drug acutely is tranquilization. The drug can be easily titrated with intravenous administration. The incidence of extrapyramidal side effects in patients receiving intravenous haloperidol for management of delirium with agitation is relatively low. Studies of the acute administration of haloperidol report an 8 to 30% incidence of extrapyramidal side effects, with akathisias being most common and acute dystonia occurring in less than 10% of patients.[36] Haloperidol can prolong the QTc interval, but this effect is clinically insignificant in most patients and does not require a pretreatment electrocardiogram. Caution is warranted with use of this agent in patients taking medications that prolong the QTc (e.g., class IA and class III antiarrhythmics, certain antibiotics, inhibitors of the cytochrome P_{450} system) and in patients with acute coronary ischemia, uncompensated congestive heart failure, or hepatic dysfunction.[37] Dosing should vary with the patient's level of agitation, age, weight, and response to treatment. In most patients, 5 to 10 mg intravenously or intramuscularly is well tolerated as an initial dose, and levels can be titrated as needed. Higher doses may be required for younger patients. Daily doses in excess of 200 mg for 15 consecutive days have been given safely to agitated patients in the critical care setting.[35] For elders, a lower initial dose of 0.50 to 1.0 mg is recommended.[38]

Several well-controlled studies have shown that the combination of haloperidol and lorazepam (given by either the intramuscular or intravenous route) can achieve more rapid control of agitated behavior than is possible with haloperidol alone and can reduce the already low incidence of extrapyramidal neuromuscular symptoms.[39,40]

The atypical antipsychotics can be used acutely for management of agitation. These drugs have multiple mechanisms of action including antagonism of alpha$_2$-adrenergic, serotonin, muscarinic, dopamine, and histamine receptors. These drugs block the reuptake of dopamine and serotonin, and the newer drugs also have dopamine agonist effects (aripiprazole).[41-44] Compared with haloperidol, several of these atypical agents (ziprasidone, risperidone, clozapine, and olanzapine) have been shown in nonrandomized case series to control agitation as effectively with less sedation and fewer extrapyramidal side effects.[41-44] Because of the limited dopamine antagonism effect, atypical antipsychotics are the preferred agent for patients with parkinsonism and agitation. Atypical antipsychotic agents for management of acute agitation have been slow to be adopted in clinical practice because of

www.ketabpezeshki.com 66485457-66963820

the limited studies (no randomized controlled studies in the ED setting) and the significant clinical experience with haloperidol and lorazepam.

It is not possible to obtain informed consent for proposed diagnostic and therapeutic interventions from a patient suffering from delirium. In such cases, implied consent exists when a true emergency is present or clinically suspected because common law recognizes that a reasonable person would want to receive treatment in a true emergency even if impaired awareness at the time of treatment precludes giving of informed consent. Thus it is appropriate to render treatment without informed consent to a patient who lacks decision-making capacity in a life-threatening emergency situation unless an advanced directive is available indicating the patient's desire to forgo treatment.[45]

Disposition

Patients with delirium secondary to acute drug intoxication may be discharged from the ED, provided the process readily reverses itself during a short period of observation and the drug has no potentially serious delayed toxicity. For most patients delirious from metabolic, infectious, or CNS processes, admission to the hospital is necessary for further diagnostic evaluation and treatment. The only readily reversible metabolic problem associated with delirium that can be completely managed in the ED is hypoglycemia.

For most patients without significant underlying medical illness who have delirium, the outcome is full recovery. After an episode of acute delirium, younger patients may experience mild cognitive dysfunction that lasts weeks to months. Geriatric patients, on the other hand, often experience persistent decline in their baseline level of functioning, with loss of at least one activity of daily living after acute delirium.[46] Delirium in elders hospitalized without baseline dementia is associated with higher 1-year mortality rates, higher rates of institutionalization, and a greater risk for development of dementia.[21,47] For elders, an episode of delirium, especially for those with baseline cognitive impairment, can have significant long-term consequences despite good supportive multidisciplinary care.[48]

DEMENTIA

Definition and Background

Dementia is not a single disease entity but rather a highly variable clinical syndrome characterized by a gradually progressive deterioration of cognitive function. As with delirium, potential causes are varied and numerous, and the prognosis depends on the underlying cause. A particular dementia can be classified as either potentially reversible or irreversible. Most patients with dementia have an irreversible disease process; during the past several years, the prevalence of reversible dementia has fallen to between 3 and 10%, with depression, hydrocephalus, subdural hematomas, drugs, and alcohol dependence syndrome accounting for a majority of cases.[49,50] The goals of ED evaluation for suspected dementia are (1) to recognize the signs and symptoms of potentially reversible forms of dementia, (2) to identify the manifestations of acute illness in the demented patient promptly, and (3) to assess the findings for congruency with the normal progression of the irreversible dementias.

In 1907, Alzheimer described the clinical history and postmortem findings for a 50-year-old woman with progressive dementia.[51] For decades, Alzheimer's disease was considered to be an uncommon dementia of younger patients known as presenile dementia. The more common dementia of elders was believed to be caused by atherosclerotic cerebrovascular disease and was referred to as senile dementia. During the past several decades, research has shown that the neuropathologic changes in the two entities are identical. Today, these two categories of primary degenerative dementias are collectively referred to as Alzheimer's disease. Alzheimer's disease accounts for 60% of all dementias; vascular dementia (with or without Alzheimer's disease) accounts for 20%, and the remaining 20% of cases are attributable to more than 50 known causes.[52]

Box 104-2 Diagnostic Criteria for Dementia

A. The development of multiple cognitive deficits manifested by both of the following:
   1. Memory impairment (impaired ability to learn new information or to recall previously learned information)
   2. One (or more) of the following cognitive disturbances:
      a. Aphasia (language disturbance)
      b. Apraxia (impaired ability to carry out motor activities despite intact motor function)
      c. Agnosia (failure to recognize or identify objects)
      d. Disturbance in executive functioning (e.g., planning, organization, sequencing, abstracting)
B. The cognitive deficits cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C. The deficits do not occur exclusively during the course of a delirium.

Adapted from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

Worldwide, approximately 24.3 million persons suffer from dementia, and 4.6 million new cases are diagnosed yearly.[52] The prevalence is approximately 1% at the age of 60 years but doubles every 5 years until it reaches 30 to 50% by the age of 85 years. The National Institutes of Health calculates that by 2030 there will be approximately 10 million people with Alzheimer's disease in the United States.[53,54]

The American Psychiatric Association has defined criteria necessary for the diagnosis of dementia (Box 104-2). There must be impairment in both memory and cognitive function. Several clinical features deserve emphasis. Intellectual impairment must involve both short-term and long-term memory. The cognitive impairment commonly involves abstract thinking, judgment, and other higher cortical functions. The cognitive disturbance must significantly interfere with interpersonal relationships, work, and social activities of the affected person. Although mild decline in intellectual functioning can be part of the normal aging process, gross intellectual impairment and confusion should not be considered part of normal aging. Mild cognitive impairment is distinct from early dementia in that impairment involves mild memory deficits; some believe that mild cognitive impairment is a precursor to the development of Alzheimer's disease.[55]

Dementia can be classified according to the degree of cognitive impairment. Mild dementia implies some impairment of work and social activities; however, the capacity for independent adequate personal hygiene and independent living remains intact. With moderate dementia, independent living is hazardous, and some degree of supervision is necessary. With severe dementia, continual supervision and often custodial care are needed.

Demented patients often have longer hospitalizations for the same acute medical illness compared with those without dementia, and the life expectancy of demented patients is 6 to 8 years less than that of nondemented age-matched control subjects.[56]

Etiology

Dementia may be caused by more than 50 different disease states (Box 104-3). Dementia may be broadly classified as either primary

Hydrocephalus
Psychiatric (pseudodementia)
Other (e.g., collagen vascular disease, paraneoplastic syndrome)

HIV-1, human immunodeficiency virus type 1.

degenerative dementia or secondary dementia; the secondary dementia category includes the potentially reversible dementias. Primary degenerative dementias include Alzheimer's disease, dementia with Lewy bodies, subcortical dementias involving the basal ganglia and thalamus (e.g., progressive supranuclear palsy, Huntington's chorea, Parkinson's disease), and dementia of the frontal lobe type, which includes Pick's disease. Dementia with Lewy bodies, clinically manifested by persistent, well-formed visual hallucinations and prominent extrapyramidal movements, has been found to be the third most common type of dementia. With advanced aging, dementia may have mixed causes, with Alzheimer's disease and vascular dementia frequently coexisting. A smaller percentage of dementias are attributable to causes such as anoxic encephalopathy, hepatolenticular degeneration, tumors, and slow virus infections.

Adverse drug reactions and metabolic abnormalities in patients can cause either an acute delirium or a gradual progressive dementia. Drug-induced dementia occurs primarily in elders and can be caused by various psychotropic drugs, antihypertensive medications, anticonvulsants, anticholinergics, and miscellaneous medications such as L-dopa. Dementia also may be caused by heavy metals and other exogenous agents, such as carbon monoxide, carbon disulfide, and trichloroethylene.

Endocrinopathies that can cause secondary dementia include hypothyroidism, hyperthyroidism, parathyroid disease, Addison's disease, Cushing's disease, and panhypopituitarism. Nutritional deficiencies that cause dementia include thiamine deficiency (Wernicke's syndrome), niacin deficiency (pellagra), vitamin B_{12} deficiency, and folate deficiency. Dementia can be caused by intracranial space-occupying lesions and hydrocephalus. Repetitive intracranial trauma resulting from contact sports can produce a chronic organic brain syndrome without evidence of hematoma or significant contusion (dementia pugilistica).[57,58] Intracranial processes that may eventually lead to a chronic organic brain syndrome include infections with slow viruses, HIV-1 infection, chronic meningitis (tubercular or fungal), brain abscess, and neurosyphilis. In addition to primary HIV-1 CNS infection, toxoplasmosis, cryptococcal meningitis, malignant disease, and infections due to herpesvirus, cytomegalovirus, varicella-zoster virus, and papovavirus (progressive multifocal leukoencephalopathy) can cause progressive cognitive impairment in this compromised group of patients and must be excluded.[59]

Depression in elders may closely mimic dementia. Diagnosis of pseudodementia or depression masquerading as dementia can be difficult and may require therapeutic interventions to confirm the clinical diagnosis of depression. Confounding the issue, depression often coexists with dementia; one study found that 40% of patients with dementia were depressed.[60] Depression, anxiety, and apathy are common in the prodrome and course of Alzheimer's disease.[60,61]

Pathophysiology

Alzheimer's disease is the best-understood dementia and involves several characteristic anatomic, pathologic, and neurochemical changes. The predominant change is cortical atrophy most prominent in the temporal and hippocampal regions caused by progressive synaptic and neuronal loss in the cerebral gray matter. This atrophy generally is followed by loss of white matter (subcortical atrophy). Cell loss does occur with the normal aging process but not to the extent seen in dementia. Not all patients with dementia have gross cerebral atrophy. There is no ischemic component to Alzheimer's disease.

Histologic features characteristic of Alzheimer's disease include extracellular deposition of β-amyloid protein and intracellular neurofibrillary tangles contributing to neuron loss. The abnormal processing of β-amyloid protein probably is central to the pathogenesis of Alzheimer's disease. The neurofibrillary tangles are intraneuronal paired helical filaments composed of the abnormally phosphorylated protein tau, the structural protein involved in the regeneration of neurites. In demented patients, these tangles occur in great numbers throughout the cerebral cortex; only limited numbers can be seen in nondemented elders (primarily in the hippocampus region) and in a variety of other diseases. The density of neocortical tangles correlates with the severity of dementia.[56] Mounting evidence suggests that Aβ protein accumulation triggers activation of cysteine aspartyl proteases (caspases) with cleaving of the tau protein, leading to neurofibrillary tangles and apoptosis. Senile plaques are extracellular lesions composed of degenerating neuronal processes and abnormal β-amyloid protein. These plaques are extensively spread throughout the cerebral cortex and do not correlate with the severity of dementia.[62] Other consistent neurohistopathologic changes in Alzheimer's disease include granulovascular degeneration, Hirano bodies, β-amyloid deposition in the small cortical blood vessels, and neuronal loss in the limbic area.[63]

Many biochemical abnormalities have been described in patients with Alzheimer's disease. A decrease in the neurotransmitter acetylcholine is characteristic. Levels of the enzyme choline acetyltransferase, which synthesizes acetylcholine in the brain, can be reduced to 20% of that in age-matched control subjects.[64]

Several risk factors for Alzheimer's disease are recognized, including advancing age, family history, low education level, hypercholesterolemia, and head trauma. The apolipoprotein E epsilon 4 allele on chromosome 19 has been associated with both familial and sporadic late-onset Alzheimer's disease. Apolipoprotein E is responsible for transporting of the cholesterol and phospholipids necessary for dendritic and synaptic repair. There are several allelic variants, but those homozygous or heterozygous for the E4 variant have an increased risk for the development and expression of the disease.[64] Abnormalities on chromosomes 1 and 14 also have been associated with Alzheimer's disease.

The frontotemporal dementias are less prevalent than Alzheimer's disease and are categorized by a frontal and temporal atrophy caused by cell death.[65] The most common histologic finding in the frontotemporal dementias is the combination of prominent cell

www.ketabpezeshki.com 66485457-66963820

loss and gliosis in frontal and temporal regions of the cortex, termed dementia lacking distinctive histology.[66]

Approximately 15 to 20% of dementias are caused by multiple vascular insults to the CNS; the resulting deficit is termed multi-infarct dementia. The multiple infarcts typically involve the cerebral hemispheres and basal ganglia. Multi-infarct dementia often has an earlier age at onset than Alzheimer's disease and occurs more often in adult men and patients who have risk factors for atherosclerosis. Approximately 29% of dementias are a mixed variety, with components of both ischemic cerebrovascular disease and Alzheimer's dementia.[64,67]

Inflammatory conditions of the CNS caused by conventional viruses include subacute sclerosing panencephalitis from measles virus infection, progressive multifocal leukoencephalopathy from infection by the JC virus (a papovavirus), progressive rubella encephalitis, and infection associated with HIV disease. The unconventional viral infections include kuru, Creutzfeldt-Jakob disease (CJD), and variant CJD (which appears to be linked to bovine spongiform encephalopathy, the pathologic process in "mad cow disease") and are associated with minimal inflammatory histopathologic changes in the CNS; these diseases cause a fine vacuolation of the nervous tissue and hence are referred to as subacute spongiform viral encephalopathies.[68]

Slow virus infections of the CNS can cause a progressive dementia that is irreversible. With these infections, months to years pass between infection with the virus and the appearance of clinical illness. Slow virus infections of the CNS are caused by both conventional viruses and unconventional viruslike agents known as prions. A prion is a proteinaceous infectious particle with the apparent ability to start a chain reaction that changes the shape of benign protein molecules into abnormal, slowly destructive forms. Prions are present in CJD and variant CJD.[68]

One of the most prevalent slow virus infections causing progressive dementia is HIV-1 infection. HIV may produce a primary neurotrophic disorder in addition to causing the immunologic compromise that permits other viruses to replicate and damage nervous tissue.

HIV dementia or AIDS dementia complex occurs in approximately one fourth of patients with AIDS. It is believed to be caused by the HIV-1 virus targeting the microglial cells and the macrophages, which may produce cytotoxic substances such as tumor necrosis factor and interleukins. Pathologic changes occur mostly in the hippocampus and basal ganglia and include atrophy, ventricular dilation, and fibrosis.[69,70]

Several of the potentially reversible causes of dementia also are associated with neuropathologic or neurochemical abnormalities. Normal-pressure hydrocephalus generally affects younger people; 50% of patients are younger than 60 years. Most of the conditions that cause hydrocephalus involve a defect in uptake of CSF by arachnoid villi, which results in gradual ventricular dilation.

Chronic, heavy ethanol consumption is associated with dementia. The neurotoxicity of ethanol appears to be independent of thiamine deficiency. Heavy chronic alcohol consumption causes cerebral cortical atrophy, but no single alcohol-related dementia syndrome exists. It is estimated that approximately 20% of chronically demented patients have a history of alcoholism.

Clinical Features

The symptoms, signs, and progression of chronic cognitive impairment rarely are so diagnostic as to permit identification of the specific cause of the dementia. Alzheimer's disease begins insidiously. Signs and symptoms of cognitive dysfunction may be present for months to years before the diagnosis is made. The earliest symptoms and signs of Alzheimer's disease often are vague and nonspecific; patients manifest anxiety, depression, insomnia, frustration, and somatic complaints that often are more prominent than the memory loss. Patients often deny any cognitive deficits and change the subject of the conversation frequently rather than admit their increasing forgetfulness. Physicians often overlook the subtle signs of dementia in this phase of the disease.[71]

Depression often is the initial manifestation of Alzheimer's disease and is present in up to 40% of cases. Early in the illness, short-term memory is affected, with forgetfulness of recent events such as appointments and names of new acquaintances. Patients often repeat questions. The memory impairment may cause them to withdraw from social situations and recreational pursuits. Attempts to perform complex tasks may produce anxiety and confusion. The patient often has difficulty with interpersonal relationships. Affect may be shallow and labile, and minor events may trigger inappropriate laughter or tears. Compensation for early deficits includes excessive orderliness and avoidance of situations in which the defects may be observed. Patients in this early phase who are treated with antidepressants with anticholinergic properties may experience worsening of their symptoms. Sedative-hypnotics prescribed for anxiety also may accelerate cognitive dysfunction.

As the dementia progresses, cognitive deficits are more obvious and should be readily apparent on a mental status examination. Problems with recent memory, impairment of remote memory, language deficits, and difficulty with spontaneous speech may be noted. With moderate severity of the disease, patients have difficulty naming objects (dysnomia). As many as 50% of patients have delusions, usually of the paranoid type. Atypical presentations of Alzheimer's disease include aphasia, visual agnosia, right parietal lobe syndrome, focal neurologic findings, extrapyramidal signs, gait disturbances, and pure memory loss. In the final stage of dementia, patients exhibit marked cognitive impairment, apraxia, and significant personality changes. They often are bedridden and unable to perform any of the routine activities of daily living.

Because Pick's disease dementia affects the frontal and temporal lobes, patients often have frontal lobe release signs, including dramatic behavioral changes of disinhibition and social inappropriateness. Basal ganglia degenerative disorders that have dementia as a prominent feature are Huntington's chorea, Parkinson's disease, and Wilson's disease. One of several features that distinguish cortical from subcortical dementias is a prominent movement disorder, including posturing, ataxia, tremor, and chorea, that tends to occur early in the illness. Other features of these dementias include slowness of speech, hypotonia, and dysarthria, which can progress to mutism.[72]

Patients with vascular dementia have a stepwise deterioration in memory and cognitive function with each cerebrovascular insult. The clinical presentation may follow one of two scenarios. In the more common scenario, the patient suffers several strokes that involve large volumes of cortical and subcortical structures in both hemispheres. The patient then exhibits dementia along with other neurologic disabilities (e.g., focal weakness, hyperreflexia, extensor plantar response). In a second group of patients, the presentation is more subtle. These patients characteristically are hypertensive and suffer multiple tiny infarcts (lacunae) that involve deep subcortical structures. There may be no focal neurologic residua except progressive dementia with psychomotor retardation. Aggressive antihypertensive therapy in the very elderly does not reduce the incidence of dementia.[73]

The clinical manifestations of slow virus CNS infections are protean. After an insidious onset of mental deterioration in subacute sclerosing panencephalitis, a rapid progression ensues that is associated with myoclonic jerks, incoordination, and ataxia. In progressive multifocal leukoencephalopathy, neurologic signs and symptoms reflect diffuse asymmetrical involvement of both cerebral hemispheres. Sporadic CJD, of unknown etiology, tends to affect older people, with a rate of disease among those 50 to 70

www.ketabpezeshki.com 66485457-66963820

years of age of 1 case per million. Among these patients, rapidly evolving dementia with myoclonus is characteristic. The hallmarks of the disorder are mental deterioration, multisystem neurologic signs, myoclonus, and typical electroencephalographic changes that evolve during months. Variant CJD affects younger patients (median age of 24 years), with key features that include early affective symptoms progressing to cognitive impairment and gait disturbances and ultimately leading to progressive neurologic deterioration. The incubation period appears to be in the range of 10 to 15 years, and most patients die within 14 months after the clinical onset of symptoms.[68]

The most common treatable dementia is pseudodementia, or depression. The clinical distinction between depression and dementia is difficult, and the coexistence of depression and dementia is common in people with mild dementia. A number of distinguishing features suggest that the problem is depression rather than dementia: the onset of cognitive changes in pseudodementia often can be pinpointed, and symptoms usually are of short duration before medical help is sought. The progression of symptoms is rapid, and the family usually is aware of the severity of the dysfunction. A history of psychiatric illness is common. Patients with pseudodementia usually complain of cognitive dysfunction and emphasize their failures and disabilities. The affective change often is pervasive, and the patient makes little effort to perform simple tasks. Loss of social skills usually occurs early in the illness, and patients communicate a strong sense of distress and inability to function. Intellectual functioning in pseudodementia often is difficult to assess because of lack of patient cooperation or inconsistent findings on neuropsychometric testing. Attention and concentration often are intact, but patients commonly give answers such as "I don't know" on tests of orientation, concentration, and memory. Memory losses for recent and remote events usually are equally severe, and variability in the performance of tasks with similar degrees of difficulty may be marked. Tasks of high capacity (e.g., testing of delayed memory with distraction) may be helpful in identifying the depressed patient.[74]

The classic triad of progressive dementia, ataxia, and urinary incontinence occurs in patients with normal-pressure hydrocephalus, which typically affects patients who are younger than those with primary degenerative dementia. More than half of the reported cases are in persons younger than 60 years. Hydrocephalus secondary to previous head trauma or infection carries a more favorable prognosis than that for primary hydrocephalus.

In approximately 20% of the reversible cases, dementia is secondary to an intracranial mass. Patients may exhibit focal or nonfocal neurologic signs.[75] Of the reversible dementias, 10 to 15% are secondary to medications or chemical intoxications, frequently compounding a history of heavy alcohol use. Geriatric patients have increased susceptibility to the toxicities owing to polypharmacy and age-related changes in metabolism. The clinical presentation of a patient with a drug-related or toxin-related dementia may be indistinguishable from that of a patient with a primary degenerative process.

Family or friends usually bring the patient to the ED because of a sudden worsening in mental status, a change in the patient's activities (e.g., refusal to eat), or a change in the ability of the caregiver to manage the patient. Presentations vary by the cause of the dementia and the stage of progression. Many elders with dementia have a superimposed delirium on presentation.

Differential Considerations

Subacute or chronic cognitive decline may be secondary to a dementing illness or can be a manifestation of senescent forgetfulness, delirium, or depression. Senescent forgetfulness is an almost inevitable reality of aging. Mild impairment of both short-term and long-term memory is usual. Unlike in dementia, the cognitive disturbance in senescent forgetfulness does not interfere with work or customary social activity. The distinction between senescent forgetfulness and mild cognitive impairment is not well defined.

In most cases, the clinical distinction between delirium and dementia is obvious. As stated previously, the onset of symptoms, progression of signs and symptoms, perceptual disturbances, possible presence of abnormalities on assessment of vital signs, and fluctuations in the level of consciousness are key distinguishing features.

Diagnostic Strategies

The evaluation of the patient with possible dementia should include a focused medical and psychiatric history and medication history plus a collateral history from family and friends. Physical examination should include a detailed neurologic examination with mental status evaluation. Dementia often goes unrecognized in the patient who is alert, pleasant, and cooperative. A validated cognitive evaluation test can play a key role in the early identification of dementia in patients who have maintained social and conversational ability.

Alzheimer's disease is a clinical diagnosis typically made on probability; no routine available laboratory tests have been found to confirm the presence of the disorder (although MRI scan, functional scans looking at regional blood flow or glucose metabolism, assay for specific biomarkers, and CSF analysis can significantly increase the probability of the presence of the disease). The physical examination is rarely helpful in detecting treatable dementias because of the considerable clinical overlap with irreversible dementias. Data clearly supporting or refuting the ordering of "routine" laboratory studies for evaluation of dementia are lacking; however, a number of studies are recommended to exclude treatable causes (Box 104-4). For patients with suspected undiagnosed dementia presenting to the ED, a baseline laboratory evaluation,

Box 104-4 Diagnostic Evaluation for Dementia

- History (patient, family, friends)
- Review of medications
- Physical examination, including neurologic evaluation
- Mental status examination
- Laboratory evaluation
  - Complete blood count
  - Electrolyte and glucose levels
  - Liver and renal function studies
  - Urinalysis
  - Thyroid function studies
  - VDRL and FTA assays
- Radiographic evaluation
  - Chest radiograph
  - Head CT scan
- Additional evaluation
  - Blood and urine screens for drugs and heavy metals
  - Erythrocyte sedimentation rate
  - HIV screen
  - Antinuclear antibody
  - Oxygen saturation, arterial blood gas analysis
  - Serum vitamin B_{12} and folate levels
  - Lumbar puncture
  - MRI head scan
  - Electroencephalogram
  - Neuropsychometric testing
  - Evoked potentials (visual, brainstem auditory, somatosensory)

CT, computed tomography; *FTA,* fluorescent treponemal antibody; *HIV,* human immunodeficiency virus; *MRI,* magnetic resonance imaging; *VDRL,* Venereal Disease Research Laboratory.

including CBC, comprehensive metabolic panel, and urinalysis, is indicated. If neurosyphilis is clinically suspected, a serum fluorescent treponemal antibody absorption test should be performed in addition to a Venereal Disease Research Laboratory (VDRL) test because the serum VDRL assay may yield negative results in patients with tertiary syphilis. The radiologic evaluation should include a non–contrast-enhanced head CT scan. The CT scan is used to diagnose or to exclude the presence of hydrocephalus or space-occupying lesions, and CT findings may support a vascular etiology for the dementia.

Patients require additional laboratory tests on follow-up evaluation; such tests may include determination of serum vitamin B_{12} and folate levels, thyroid function studies, estimation of erythrocyte sedimentation rate, fluorescent antinuclear antibody assay, measurement of urine corticosteroid levels, and, if indicated by history, urine screens for drugs and heavy metals. Selected patients should undergo a lumbar puncture with CSF analysis, MRI, positron emission tomography scan, electroencephalography (in CJD, characteristic slowing and periodic complexes may be electroencephalographic features), neuropsychological testing, and testing of visual evoked potentials, brainstem auditory evoked potentials, and somatosensory evoked potentials. The EEG rarely is helpful in establishing the diagnosis of senile dementia. An MRI finding of medial temporal atrophy suggests Alzheimer's disease but is not specific or sensitive for diagnosis of this disorder.[76]

Treatment and Disposition

Reversible dementias and conditions that cause worsening of baseline dementia require early diagnosis and treatment of the underlying disorder if previous cognitive function is to be restored. Determination of reversible causes of dementia during the ED evaluation occasionally is possible on the basis of the history (including medication history), physical examination, and head CT scan. Patients with acute changes in mental status or a relatively rapid onset of symptoms will require hospitalization for comprehensive evaluation. Patients presenting with recent gradual decline in cognitive function without an underlying acute medical condition can undergo further evaluation on an outpatient basis.

Pharmacotherapy approved by the FDA for the treatment of mild to moderate Alzheimer's disease includes the cholinesterase inhibitors donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). There are multiple randomized, placebo-controlled, large-scale clinical trials with these drugs establishing efficacy in improving cognitive functions, overall evaluation, and activities of daily living in patients with mild to moderate dementia. These drugs are not considered disease modifying, and there are limited data at present on the benefit of these drugs beyond 2 or 3 years (a significant number of patients discontinue medications because of side effects). The most common side effect of these agents is due to the cholinergic effects, including nausea, vomiting, and diarrhea. In 2003, the FDA approved memantine (Namenda), a disease-modifying agent that helps regulate the excitatory effects of glutamate by antagonizing the *N*-methyl-D-aspartate receptor. Whether this drug alters the underlying disease process is unclear, but short-term studies show improved cognition in patients with moderate and moderate to severe Alzheimer's disease with memantine.[77,78] There are conflicting studies on the effectiveness of other agents, such as gingko biloba, vitamin E, nonsteroidal agents, and statins. Estrogen replacement is not indicated for cognitive improvement or maintenance in women with Alzheimer's disease and can be detrimental. Ultimately, the key to altering the course of the disease is halting neuron loss. In severe dementia, the goal of management is supportive care.

Many therapies currently are under investigation for the modulation and early treatment of Alzheimer's disease. These therapies include antibiotics (directed against *Chlamydophila pneumoniae*), secretase modulators to reduce serum β-amyloid levels, immunization to reduce amyloid plaque burden, chelators to promote dissolution of β-amyloid, nonsteroidal anti-inflammatory medications, supplementation with omega-3 fatty acids, and testosterone.[79,80]

Increasing evidence suggests that certain nonpharmacologic measures, including behavioral methods and avoidance of environmental triggers, may be effective in reducing agitation and anxiety in patients with dementia.[81] On occasion, medications are needed for behavioral symptoms of dementia. Affected patients typically do not improve with anxiolytics. Adverse effects offset the modest advantages in the efficacy of antipsychotic drugs for the treatment of psychosis, aggression, or agitation in many patients with Alzheimer's disease, and these drugs should be avoided when possible.[82,83] However, agitation can be controlled with a small dose of the butyrophenone haloperidol.[84] The cardiovascular toxicity of this drug is minimal, and it is reasonably well tolerated in elders. Clozapine also has been shown to be effective in treating psychosis associated with both Alzheimer- and Parkinson-type dementias.[85] In April 2005, the FDA issued a black box warning that the use of atypical antipsychotics to treat elderly patients with dementia was associated with an increased risk for death compared with placebo. Atypical antipsychotics are relatively contraindicated in this group of patients because of the association with an increased risk of hospitalization and death.[86,87] Agitation may occasionally be due to unrecognized depression in dementia, and a trial of selective serotonin reuptake inhibitors may be warranted.[88] Temazepam (Restoril) is the drug of choice for sleep disturbance. The half-life of temazepam is 8 to 10 hours for patients of all ages, and the drug bypasses the oxidative hepatic enzyme system.

On occasion, patients are brought to the ED because of a crisis due to family stress from continuous care of the person with dementia. A brief nursing home stay or other institutional stay (respite program) may give the family time to mobilize resources to resume the home care regimen. Social workers can play a vital role in attempting to facilitate management of these patients.

KEY CONCEPTS

- Delirium is an acute condition characterized by an altered level of consciousness, disorganized thinking, and inattention. It develops during a short time, and symptoms tend to fluctuate during hours to days. A thorough investigation of possible causes of the delirium should be undertaken in the ED.
- Dementia is a chronic condition characterized by memory loss and cognitive impairment. It is slow in onset and progressive in nature. This disorder has many causes, several of which are reversible with treatment. It is essential to resist the temptation to classify dementia as a "futile" disease, and a search for underlying medical conditions that may be worsening a dementing illness is indicated.
- Patients with either dementia or psychiatric disorders may present with superimposed delirium, often making identification of the underlying cause of their abnormal behavior difficult. When the diagnosis is in doubt, possible causes of delirium should be specifically excluded.
- The clinician should be wary of attributing behavioral disturbances to psychiatric illness in the presence of abnormal vital signs or abnormal sensorium.

Chapter 105

Brain and Cranial Nerve Disorders

Brian A. Stettler

This chapter discusses cranial nerve problems, cerebral venous thrombosis, and multiple sclerosis—neurologic disorders that often provide significant diagnostic and therapeutic challenges in the emergency department (ED) setting (Table 105-1).

TRIGEMINAL NEURALGIA

Perspective

Trigeminal neuralgia, or tic douloureux, is a syndrome featuring painful paroxysms in one or more distributions of the trigeminal nerve. Trigeminal neuralgia is relatively uncommon, with an annual incidence of 4 to 13 cases per 100,000 population.[1,2] It is more common in women than in men, with a female-to-male ratio of 1.7 : 1. Affected persons typically are between 50 and 69 years of age, and symptoms occur more frequently on the right side of the face.[3]

Pathophysiology

Trigeminal neuralgia is an idiopathic disorder, although significant evidence points to vascular compression of the trigeminal nerve root in many cases. This compression commonly is caused by a tortuous arterial or venous loop in the posterior fossa, an arteriovenous malformation, or rarely a tumor. In surgical case series, vascular compression of the trigeminal nerve root is found in 80 to 90% of cases.[4,5] Of note, however, structural lesions are not found in all patients with trigeminal neuralgia.[6]

Clinical Features

Trigeminal neuralgia is manifested with unilateral facial pain, typically characterized as lancinating paroxysms of pain in the lips, teeth, gums, or chin. The pain of trigeminal neuralgia is commonly associated with physical triggers such as chewing, brushing the teeth, shaving, washing or touching the affected area of the face, swallowing, or exposure to hot or cold temperature in the affected area. The maxillary and mandibular divisions of the trigeminal nerve are most commonly involved; rarely, the ophthalmic division alone is involved. Patients tend to experience the pain in clustered episodes that last a few seconds to several minutes. The attacks can occur during the day or night but rarely arise during sleep.[6,7]

Diagnostic Strategies

A careful history and physical examination should be performed to rule out other painful facial conditions, including odontogenic infections, sinus disease, otitis media, acute glaucoma, temporomandibular joint disease, and herpes zoster. Patients who lack local pathologic findings to explain the painful syndrome require a careful neurologic examination. The presence of a neurologic deficit should prompt suspicion of a structural lesion, such as aneurysm, tumor, or other intracranial lesion (e.g., from multiple sclerosis). Of note, 2 to 4% of patients with trigeminal neuralgia also have multiple sclerosis.[8] Patients with normal findings on the head and neck examination and no neurologic deficits who have episodic, unilateral facial pain associated with nonpainful triggers are likely to have trigeminal neuralgia.

Management

Since the 1960s the treatment of choice for trigeminal neuralgia has been the anticonvulsant medication carbamazepine. The purported effectiveness of this treatment, however, is based on uncontrolled studies, and the mechanism of action of anticonvulsant therapy for trigeminal neuralgia is unclear. The true efficacy of medical therapy is difficult to assess owing to a high rate of spontaneous remission. Nonetheless, carbamazepine appears to be an effective and well-tolerated agent for treatment of trigeminal neuralgia. The initial dosage of carbamazepine is 100 mg twice daily; this dose is then increased to three times daily after 1 week. The dose may be increased by 100 mg/day, up to a maximum of 1200 mg/day. A complete blood count and liver function studies are performed periodically in patients who are taking carbamazepine to monitor for hematologic and hepatic side effects. Additional agents that have been used for treatment of trigeminal neuralgia include phenytoin, baclofen, valproate sodium, lamotrigine, gabapentin, and levetiracetam. None of these drugs has been shown to be more effective than carbamazepine.[7]

Surgical management has been a therapeutic option since the 1950s. Surgical procedures include both peripheral and central procedures. Peripheral strategies include medication injection and cryotherapy techniques designed to temporarily block or permanently ablate branches of the peripheral trigeminal nerve. Although these procedures are relatively effective initially, recurrence is common. Repeated nerve blocks are not recommended because of a high risk of permanent facial anesthesia.

Central procedures can be divided into percutaneous approaches and open approaches. Percutaneous destruction of the trigeminal ganglion can be done by means of radiofrequency ablation, thermal ablation, glycerol injection, or balloon microcompression. These procedures carry the risk of corneal anesthesia, oculomotor paresis, or masticatory weakness.[9]

Open surgical management is the surgical option of choice in many treatment centers. Open surgical procedures include

Table 105-1 The Cranial Nerves: Normal Function and Pathologic Considerations

CRANIAL NERVE	CLINICAL FUNCTION RELEVANT TO EMERGENCY MEDICINE	PATHOLOGIC FEATURES	POSSIBLE CAUSES
Cranial nerve I: Olfactory nerve	Sense of smell	Unilateral anosmia	Trauma: Skull fracture or shear injury interrupting olfactory fibers traversing the cribriform plate Tumor: Frontal lobe masses compressing the nerve
Cranial nerve II: Optic nerve	Vision	Unilateral vision loss	Trauma: Traumatic optic neuropathy *Tumor:* Orbital compressive lesion *Inflammatory:* Optic neuritis (MS) *Ischemic:* Ischemic optic neuropathy
Cranial nerve III: Oculomotor nerve	Extraoculomotor function via motor fibers to levator palpebrae, superior rectus, medial rectus, inferior rectus, inferior oblique muscles Pupillary constriction via parasympathetic fibers to constrictor pupillae and ciliary muscles	Ptosis caused by loss of levator palpebrae function Eye deviated laterally and down Diplopia Dilated, nonreactive pupil Loss of accommodation	*Trauma:* Herniation of the temporal lobe through the tentorial opening, causing compression and stretch injury to the nerve *Ischemic:* Especially in diabetes Microvascular ischemic injury to nerve causes extraocular muscle paralysis but usually is papillary sparing (often painful) *Vascular:* Intracranial aneurysms may press on the nerve, leading to dysfunction Myasthenia gravis can lead to atraumatic ocular muscle palsy
Cranial nerve IV: Trochlear nerve	Motor supply to the superior oblique muscle	Inability to move eye downward and laterally Diplopia Patients tilt head toward unaffected eye to overcome inward rotation of affected eye	Trauma is the most common cause of nerve dysfunction
Cranial nerve V: Trigeminal nerve	Motor supply to muscles of mastication and to tensor tympani Sensory to face, scalp, oral cavity (including tongue and teeth)	Partial facial anesthesia Episodic, lancinating facial pain associated with benign triggers such as chewing, brushing teeth, light touch	*Trauma:* Facial bone fracture may injure one section, leading to area of facial anesthesia Tic douloureux
Cranial nerve VI: Abducens nerve	Motor supply to the lateral rectus muscle	Inability to move affected eye laterally Diplopia on attempting lateral gaze	*Tumor:* Lesions in the cerebellopontine angle Any lesion, vascular or otherwise, in the cavernous sinus may compress nerve *Elevated intracranial pressure (ICP):* Because of its position and long intracranial length, increased ICP from any cause may lead to injury and dysfunction of the nerve
Cranial nerve VII: Facial nerve	Motor supply to muscles of facial expression Parasympathetic stimulation of the lacrimal, submandibular, and sublingual glands Sensation to the ear canal and tympanic membrane	*Hemifacial paresis*: *Lower motor neuron lesion* leaves entire side of face paralyzed *Upper motor neuron lesion* leaves forehead musculature functioning Abnormal taste Sensory deficit around ear Intolerance to sudden loud noises	*Lower motor neuron:* *Infection (viral):* The likely cause of Bell's palsy *Lyme disease:* The most common cause of bilateral cranial nerve VII palsy in areas where Lyme disease is endemic Bacterial infection extending from otitis media *Upper motor neuron:* Stroke, tumor
Cranial nerve VIII: Vestibulocochlear nerve	Hearing and balance	Unilateral hearing loss Tinnitus Vertigo, unsteadiness	*Tumor:* Acoustic neuroma Mimics Ménière's disease, perilymphatic fistula
Cranial nerve IX: Glossopharyngeal nerve	General sensation to posterior third of tongue Taste for posterior third of tongue Motor supply to the stylopharyngeus	Clinical pathology referable to the nerve in isolation is very rare Occasionally painful paroxysms beginning in the throat and radiating down the side of the neck in front of the ear but behind the mandible	Brainstem lesion Glossopharyngeal neuralgia

Table 105-1 The Cranial Nerves: Normal Function and Pathologic Considerations—cont'd

CRANIAL NERVE	CLINICAL FUNCTION RELEVANT TO EMERGENCY MEDICINE	PATHOLOGIC FEATURES	POSSIBLE CAUSES
Cranial nerve X: Vagus nerve	Motor to striated muscles and muscles of the pharynx, larynx, and tensor (veli) palatini Motor to smooth muscles and glands of the pharynx, larynx, thoracic and abdominal viscera Sensory from larynx, trachea, esophagus, thoracic and abdominal viscera	*Unilateral loss of palatal elevation*: Patients complain that on drinking liquids, the fluid refluxes through the nose *Unilateral vocal cord paralysis*: Hoarse voice	Brainstem lesion Injury to the recurrent laryngeal nerve during surgery
Cranial nerve XI: Spinal accessory nerve	Motor supply to the sternocleidomastoid and trapezius muscles	Downward and lateral rotation of the scapula and shoulder drop	Trauma to the nerve
Cranial nerve XII: Hypoglossal nerve	Motor supply to the intrinsic and extrinsic muscles of the tongue	*Tongue deviations*: *Upper motor neuron lesion* causes the tongue to deviate toward the opposite side *Lower motor neuron lesion* causes the tongue to deviate toward the side of the lesion, and the affected side atrophies over time	Stroke or tumor can cause upper motor neuron lesion Amyotrophic lateral sclerosis can cause bilateral lower motor neuron lesion with atrophy Metastatic disease to the skull base may involve the nerve

microvascular decompression of the nerve with or without partial ablation. Although the open microvascular decompression procedure has proved to be effective, with pain relief achieved in 80 to 95% of patients, the surgery is associated with the risk of significant complications, including hearing loss, facial anesthesia, cerebrospinal fluid (CSF) leak, brainstem or cerebellar injury, headaches, meningitis, and death.[10,11] Gamma Knife radiosurgery, a minimally invasive, precision-directed stereotactic radiosurgery, also has been associated with good outcomes. This highly specialized technique requires extremely sophisticated stereotactic radiofrequency equipment and is available only in specialized centers, but in many cases it has similar results for pain relief without the morbidity associated with open procedures in patients who might otherwise be a surgical risk.[12-14]

Disposition

Patients with suspected trigeminal neuralgia should be referred for specialty evaluation. Patients with a neurologic deficit require urgent imaging studies, typically magnetic resonance imaging (MRI), to rule out a mass or vascular abnormality.

FACIAL NERVE PARALYSIS

Perspective

The acute onset of facial nerve paralysis often will prompt an ED visit. Fortunately, early diagnosis and therapy may improve the patient's chance for recovery of function of the facial nerve. Facial nerve paralysis of acute onset affects approximately 20 to 25 persons per 100,000 population per year, without geographic, gender, or race predilection.[15,16]

Principles of Disease

The facial nerve innervates the muscles of facial expression and the muscles of the scalp and external ear in addition to the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric muscles. The sensory portion of the nerve supplies the anterior two thirds of the tongue with taste and sensation to portions of the external auditory meatus, soft palate, and adjacent pharynx. The parasympathetic portion supplies secretomotor fibers for the submandibular, sublingual, lacrimal, nasal, and palatine glands.[17]

The nerve originates from the pontomedullary junction of the brainstem and enters the internal auditory meatus with cranial nerve VIII. Within the temporal bone, the facial nerve has four major branches: the greater and lesser superficial petrosal nerves, the nerve to the stapedius muscle, and the chorda tympani. The facial nerve exits the temporal bone at the stylomastoid foramen and then enters the parotid gland, where it divides to supply the muscles of facial expression.[17,18]

Pathophysiology

The three main causes of facial nerve paralysis that are relevant to emergency medicine are grouped into infectious, traumatic, and neoplastic.

Infection

Bell's Palsy. Bell's palsy, also commonly called idiopathic facial paralysis, has long been postulated to have a viral cause. This disease entity is characterized by an abrupt onset of a lower motor neuron paresis that can progress during 1 to 7 days to complete paralysis. A prodromal illness is described by 60% of patients. Symptoms and signs frequently associated with the facial paresis include ear pain, perception of sensory change on the involved side of the face, decreased tearing, overflow of tears on the cheek (epiphora), abnormally acute hearing (hyperacusis), and impairment or perversion of taste (dysgeusia).[19]

Treatment approaches can be medical or surgical. The primary medical therapies for Bell's palsy center on reducing inflammatory changes to the nerve with corticosteroids and treating the presumed viral cause. If these therapies are unsuccessful, surgical decompression may be considered.

Available evidence now strongly favors the use of corticosteroids for the treatment of Bell's palsy, and earlier treatment is associated with better efficacy and outcomes.[20-24] The rationale for this application of steroid therapy is that edema of the nerve, confined within the facial canal, is thought to cause or contribute to the nerve injury. On the basis of this theory, most experts currently recommend a course of prednisone with an initial dose of 1 mg/kg per day for 7 to 10 days, with or without a short

www.ketabpezeshki.com 66485457-66963820

taper.[15,18,25,26] The most definitive randomized, double-blind, placebo-controlled trial involving 496 patients showed an improvement in complete recovery of facial nerve function at 3 months from 64% with placebo to 83% with the use of prednisolone in a dose of 25 mg by mouth twice daily.[27] Therapy should be started as soon as possible, ideally within the first 24 hours, but it is still recommended for patients without contraindications who seek treatment within 1 week of symptom onset.[25]

A number of studies have supported the contention that Bell's palsy may be caused by herpes virus infection. One study demonstrated herpes simplex virus type 1 DNA in the endoneurial tissue of 11 of 14 patients with Bell's palsy but not in control subjects.[28] In a trial of prednisone and acyclovir in 99 patients, patients treated with prednisone and acyclovir had a more favorable recovery than that observed in patients receiving prednisone alone.[29] A study of 296 patients with Bell's palsy treated with valacyclovir or placebo in addition to a fixed dose of prednisolone found significant benefit to the addition of valacyclovir, particularly in the setting of severe palsy or in those treated within 24 hours of symptom onset.[30] Other studies have found conflicting results. Despite a lack of overwhelming evidence, the addition of an antiviral agent should be considered in the treatment of Bell's palsy, especially with severe loss of function. The most commonly recommended antiviral regimen is valacyclovir, 1000 mg orally two times daily for 10 days. Valacyclovir and famciclovir have better oral absorption, are better tolerated, and are dosed less frequently, resulting in higher compliance than with acyclovir treatment.[18,25,26,28,31] As with steroid therapy, although earlier treatment is preferred, treatment should be considered for patients presenting within 1 week of symptom onset.

Ramsay Hunt Syndrome. Ramsay Hunt syndrome (herpes zoster oticus) is characterized by unilateral facial paralysis, a herpetiform vesicular eruption, and vestibulocochlear dysfunction. The vesicular eruption may occur on the pinna, external auditory canal, tympanic membrane, soft palate, oral cavity, face, and neck as far down as the shoulder. The pain is considerably more severe than that associated with Bell's palsy, and it frequently is out of proportion to physical findings. In addition, outcomes are worse than with Bell's palsy, with a lower incidence of complete facial recovery and the possibility of sensorineural hearing loss. Therapy is similar to that for Bell's palsy. Both prednisone and antiviral therapy for 7 to 10 days are advocated.[18,32,33]

Lyme Disease. Lyme disease is the most frequent vector-borne infection in the United States. It is caused by the spirochete *Borrelia burgdorferi* and is spread by the bite of *Ixodes* genus ticks. Neurologic manifestations can arise in any phase of the disease, and the incidence of facial palsy in patients with neurologic involvement is 35 to 51%. In regions in which Lyme disease is endemic, it has been shown to be the leading cause of facial paralysis in children, responsible for half of all pediatric cases of facial nerve paralysis.[34,35]

Bilateral facial nerve paralysis is rare but can occur with systemic infections. The two diseases most commonly associated with bilateral simultaneous onset of facial paralysis are Lyme disease and infectious mononucleosis. Bilateral facial paralysis should be considered to be a manifestation of Lyme disease until further testing excludes this diagnosis.[26,34-36] The evaluation and treatment of Lyme disease are discussed in Chapter 134.

Bacterial Infections. Facial paralysis can be caused by acute bacterial infections of the middle ear, mastoid, or external auditory canal. In the pre-antibiotic era, facial paralysis was associated with acute otitis media in approximately 2% of cases; today, however, it occurs in only 0.2% of cases. Treatment consists of intravenous antibiotics and myringotomy for decompression. Malignant otitis externa can be associated with facial paralysis. This disease entity is most commonly seen in immunocompromised patients and usually is caused by *Pseudomonas* infection. Treatment involves prolonged intravenous antipseudomonal antibiotic therapy and may require surgical débridement.[26,37]

Trauma

In patients with head trauma, the facial nerve is the most commonly injured cranial nerve. The cause generally is a temporal bone fracture with nerve transection. Surgical exploration is warranted if there is firm evidence that the nerve has been transected, indicated by a sudden onset of complete unilateral facial paralysis, loss of electrical activity, and evidence of a displaced fracture involving the facial canal.

Neoplasm

Tumors of the facial nerve itself or tumors anywhere along the course of the facial nerve that invade or compress the nerve may lead to facial paralysis. The course is typically progressive for at least 3 weeks. A sudden onset of paralysis, however, does not rule out an underlying tumor because facial paralysis secondary to a neoplasm is of sudden onset in approximately 25% of cases.[38] A neoplastic cause should be suspected in patients who suffer from recurrent ipsilateral facial paralysis, significant pain, prolonged symptoms, or any other concomitant cranial nerve abnormality.

Clinical Features and Differential Considerations

The medical history in patients with facial paralysis focuses on onset of the paralysis, concentrating on timing and rapidity of onset and associated signs and symptoms. A rapid onset of facial paralysis with dysgeusia and hyperacusis preceded by a viral prodrome is suggestive of Bell's palsy. A history of recurrent ipsilateral paralysis or slow progression of symptoms is more characteristic of a tumor. Associated cranial nerve abnormalities, although occasionally seen with Bell's palsy, also point to the possibility of a tumor or ischemic insult. The Ramsay Hunt syndrome causes significant pain and a vesicular rash, although the rash may follow the facial paresis by a few days. Significant anatomic abnormalities on visual or otoscopic inspection of the ipsilateral ear will be found with bacterial otitis media and otitis externa. Finally, systemic symptoms or bilateral facial paresis, especially in endemic areas, should raise the possibility of Lyme disease.

Diagnostic Strategies

The diagnostic workup of acute facial nerve paresis is based on whether the clinical picture is suggestive of a disease process other than Bell's palsy. If the clinical history is classic for Bell's palsy, no imaging or laboratory studies are required. Of note, any history of possible exposure warrants serologic evaluation for Lyme disease. Although outpatient testing including electroneurography may ultimately be performed, this usually is not part of the initial evaluation.

The presence of a "central" seventh nerve paralysis (upper face sparing) should prompt imaging with computed tomography (CT) or MRI, and consideration should be given to the possibility of an acute stroke or other hemispheric lesion. History or physical examination findings suggestive of a possible tumor require imaging to rule out a neoplasm. The study of choice will depend on the institution and preferences of the consultant.

Disposition

Most patients who have a seventh nerve paralysis will have a clinical diagnosis of Bell's palsy and may be discharged with referral

www.ketabpezeshki.com 66485457-66963820

for short-term follow-up. Patients with a possible hemispheric process, such as stroke or tumor, require further evaluation and usually hospitalization. Patients thought to have Lyme disease require immediate initiation of appropriate antibiotic therapy.

In patients with a peripheral facial nerve paralysis, the ipsilateral eye should be patched, and consideration should be given to ophthalmologic follow-up because there is a high rate of corneal abrasions and corneal dryness associated with the inability to blink properly or to close the eye completely.

VESTIBULAR SCHWANNOMA

Perspective

Vestibular schwannoma, formally referred to as acoustic neuroma, is a rare but important cause of sensorineural hearing loss. The annual incidence of vestibular schwannoma is 1 case per 100,000 population, with a mean age at the time of detection of 46 to 58 years.[39] The female-to-male ratio is 1.5 : 1. Vestibular schwannoma is rarely bilateral, occurring in this form in approximately 5% of cases and generally associated with type 2 neurofibromatosis. Although histologically benign, vestibular schwannoma can cause neurologic damage by direct compression on the eighth cranial nerve and the other structures in the cerebellopontine angle.[40]

Principles of Disease

Vestibular schwannoma arises from the Schwann cells covering the vestibular branch of the eighth cranial nerve as it passes through the internal auditory canal. The tumor may compress the cochlear (acoustic) branch of the eighth cranial nerve, causing hearing loss, tinnitus, and dysequilibrium. Continued growth of the tumor may result in compression of structures in the cerebellopontine angle, where the facial and trigeminal nerves may be compressed and damaged. Larger tumors may further encroach on the brainstem and if large enough may compress the fourth ventricle, ultimately resulting in signs of increased intracranial pressure (ICP).[41]

Clinical Features

Asymmetrical sensorineural hearing loss is the hallmark of vestibular schwannoma. Up to 15% of patients with this tumor, however, will have normal results on audiometry. These patients typically have symptoms such as unilateral tinnitus, imbalance, headache, fullness in the ear, otalgia, and facial nerve weakness. Thus, patients with asymmetrical symptoms should be further evaluated for vestibular schwannoma even with normal findings on audiometry.[42]

Vestibular schwannomas are extremely slow-growing tumors, averaging an approximately 1-mm increase per year, although many do not grow at all on serial examinations.[43] Symptom onset is therefore generally gradual. In one series of 126 cases, the average time from symptom onset to discovery of a vestibular schwannoma was approximately 4 years.[44]

Diagnostic Strategies

When vestibular schwannoma is suspected, the patient is evaluated by audiometry or gadolinium-enhanced MRI. This imaging technique is extremely sensitive and has led to earlier diagnosis and a decrease in mean size at detection of vestibular schwannoma. CT lacks the necessary sensitivity in the posterior cranial fossa to reliably rule out the presence of vestibular schwannoma. The smaller the tumor at the time of diagnosis, the more options there are for therapy and the better the potential prognosis.[40]

Differential Considerations

A majority of disease entities included in the differential diagnosis for vestibular schwannoma cause symmetrical sensorineural hearing loss. Asymmetrical sensorineural hearing loss has few causes other than vestibular schwannoma. Ménière's disease may present a diagnostic dilemma because it can be asymmetrical. Ménière's disease may be differentiated from vestibular schwannoma in that the tinnitus of Ménière's disease usually is intermittent, whereas the tinnitus of vestibular schwannoma typically is continuous. In addition, patients with Ménière's disease typically describe true vertigo, whereas patients with a vestibular schwannoma are more likely to describe imbalance or dysequilibrium.

Vestibular schwannomas account for 80% of all cerebellopontine angle tumors. Among all other lesions, meningioma is the most common. Meningiomas more frequently cause symptoms of facial palsy or trigeminal nerve abnormality. Of note, however, considerable similarity between the clinical picture of a meningioma and that of vestibular schwannoma in the cerebellopontine angle has been described.[45]

Management

Vestibular schwannoma may be removed surgically or ablated with stereotactic radiation therapy. In general, tumors larger than 3 cm are recommended for microsurgery because radiation treatments, such as with the Gamma Knife or linear accelerator, are less effective for local control and growth arrest in larger masses. Smaller tumors are amenable to use of stereotactic radiation therapy, which has greater salvage rates of facial nerve function and hearing.[46,47] Stereotactic radiation therapy generally has good long-term outcomes of local growth arrest, with nerve salvage approaching 90% or greater. Injuries to the trigeminal, facial, and acoustic nerves and to the cerebellum are possible complications of both procedures. In patients who are minimally symptomatic with small tumors, serial monitoring with MRI is a viable nonsurgical option. All patients should be evaluated by a specialist in the evaluation and treatment of vestibular schwannoma because smaller tumor size at detection is associated with a better long-term outcome.[39,43]

Disposition

Patients with suspected acoustic neuroma should be referred for audiometry or MRI and evaluation by a specialist in either otolaryngology or neurosurgery.

DIABETIC CRANIAL MONONEUROPATHY

Perspective

Cranial mononeuropathies occur uncommonly, usually are a complication of diabetes, and most often affect the extraocular muscles. The oculomotor nerve is most commonly affected, followed in order by the trochlear and abducens nerves. In one large series in Japan, the incidence of cranial nerve palsies was 1.0% among diabetics and 0.1% among nondiabetics.[48,49] Whereas ophthalmoplegia appears to be closely related to diabetes, facial palsy is less strongly correlated with this disease.[48,50]

Principles of Disease

The pathologic basis of diabetic mononeuropathy appears to be ischemia of the affected cranial nerve caused by occlusion of an intraneural nutrient artery serving the nerve. This occlusion leads

www.ketabpezeshki.com 66485457-66963820

to injury located primarily in the center of the nerve because the core fibers are more dependent on the supply from such nutrient arteries. The peripheral fibers are less affected because they also are supplied by collateral vessels. In the oculomotor nerve, the preservation of the circumferentially located parasympathetic fibers explains the pupillary sparing that usually is found in this syndrome. In two studies, the microvascular changes in the intraneural arteries that lead to occlusion were noted in diabetic patients but absent in nondiabetics.[51,52]

Clinical Features

Patients typically describe acute onset of unilateral retro-ocular and supraorbital pain, diplopia, and ptosis.[49] The physical manifestations of a third cranial nerve palsy include the inability to move the eye superiorly and medially, accompanied by ptosis. The pupillary light reflex usually is present. Although it is a less common finding, the fourth and sixth cranial nerves may be affected. Patients with a fourth cranial nerve palsy are unable to move the eye inferolaterally, and those with a sixth cranial nerve palsy are unable to move the eye laterally. Because of the long intracranial course of the sixth nerve, a patient with an isolated sixth nerve palsy should be evaluated for an intracranial lesion or increased ICP.[53]

Differential Considerations

Evaluation of cranial nerve dysfunction requires a thorough history and physical examination and cranial imaging, usually with MRI. Diabetic mononeuropathy should be considered a diagnosis of exclusion. Considerations in the differential diagnosis include trauma, tumor, vertebrobasilar ischemia, aneurysm, and hemorrhage into the brainstem.[54]

Management

Treatment consists of patching of the affected eye and administration of analgesics and antiplatelet therapy. The prognosis is good. If the neuropathy does not begin to resolve within 3 to 6 months or if more than one nerve is affected, another cause should be sought. Complete resolution is expected within the first year. Antioxidant preparations, including α-lipoic acid, have been used therapeutically and have not shown harm, but such agents have yet to be shown to have convincing clinical effect.[55]

CEREBRAL VENOUS THROMBOSIS

Perspective

No exhaustive studies of the epidemiology of cerebral venous thrombosis (CVT) have been performed. In case series, the median patient age is 38 years; women represent 60 to 75% of those diagnosed.[56,57]

Principles of Disease

Cerebral blood is drained by several major veins that lead into the dural sinuses. The major dural sinuses are the superior sagittal sinus, the inferior sagittal sinus, the straight sinus, the lateral sinuses, and the sigmoid sinuses. The variability in symptoms and signs in patients who present with CVT stems from differences in thrombus location and acuity of thrombus formation. Symptoms of intracranial hypertension, especially headache, are present in most patients with sinus thrombosis, whereas those with thrombosis of the cerebral veins are thought to be more prone to hemorrhagic infarction and localizing neurologic deficits.[58] As with venous thrombosis in other locations, multiple causes and predisposing factors for CVT are recognized. Underlying causes are often divided into infectious and noninfectious categories. Infectious causes include local infections, such as sinusitis, otitis media, facial cellulitis, and systemic infections. Noninfectious causes include direct injury to the cerebral venous system from trauma, surgery, dehydration, or any other condition that may predispose the patient to development of a hypercoagulable state, including the presence of a malignant neoplasm or the use of oral contraceptive agents.[59]

Clinical Features

The symptoms and signs associated with CVT are varied. Headache is the primary feature of CVT in 74 to 92% of affected patients.[59,60] Papilledema is noted in 28 to 45% of cases.[57,60,61] Lethargy, decreased level of consciousness, or mental status changes may be noted. Seizures occur in 35 to 50% of patients in the acute phase.[57,59,61,62] In addition to the location and acuity of thrombosis formation, a patient's symptom onset will vary in accordance with the extent of collateral vessel growth in the venous territory. Early thrombotic changes may be well compensated for by the collateral venous drainage. Symptoms will appear only when the compensation for venous thrombosis is no longer sufficient or when hemorrhagic infarction occurs. Variability in collateralization between patients also adds to the variability and time course of symptoms. Two national and international observational studies documented an average time from symptom onset to diagnosis of 7 days, reflecting the difficulty in diagnosis of this rare disease entity.[57,61,63] The reported incidence of focal neurologic signs, including seizures, on clinical examination varies widely between series, ranging from 25 to 71%.[59,60] Because of the broad spectrum of possible clinical features, the diagnosis of CVT may be difficult but should be a consideration in any patient with unexplained headache, especially in combination with focal neurologic deficit, papilledema, or seizures.

Diagnostic Strategies

Cerebral angiography no longer plays a significant role in the diagnosis of CVT. Both MRI and CT scan with venous-phase imaging have been evaluated as both primary and definitive imaging modalities for the diagnosis of CVT. CT scanning is useful in the initial workup of the patient with possible CVT, but non–contrast-enhanced CT is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis. Findings on CT that are consistent with CVT include hyperdensity of a thrombosed sinus or deep vein (referred to as the cord sign or attenuated vein sign, respectively), brain edema, and hemorrhage secondary to venous congestion. Whereas non–contrast-enhanced CT in the diagnosis of CVT has been evaluated only in case series, the published sensitivity and specificity typically range from 65 to 100% when it is evaluated against MRI as the "gold standard."[64]

Similar to CT scanning, MRI also can demonstrate local changes secondary to venous congestion, such as brain edema and hemorrhage. In addition, MRI can demonstrate the possibility of CVT by the lack of a "flow void." On conventional MRI, a flow void indicates the presence of moving blood within the sinus, whereas the absence of a flow void indicates a possible thrombus. Diagnostic accuracy, however, is greatly improved through use of magnetic resonance venography (MRV). This technique takes advantage of the MRI signal characteristics of flowing blood to create images of venous structures. Combination of these imaging techniques further enhances diagnostic accuracy. For imaging of a particular dural sinus, presence of the sinus on conventional MRI and lack of flow on MRV are diagnostic of a sinus thrombosis. This

www.ketabpezeshki.com 66485457-66963820

combined approach has diagnostic sensitivity similar to that of conventional angiography.[59,65]

Several studies show similar sensitivity between MRV and CT venography for the diagnosis of CVT when the CT study is performed on a multidetector row CT scanner. These studies, involving several hundred patients, showed sensitivity of CT venography for CVT that approached 100% and was comparable to that of MRV both in sensitivity and in inter-rater reliablity.[66-69] The sensitivity of CT venography performed by scanners that do not use multidetector row technology is unknown.

Several small studies have attempted to evaluate the usefulness of the D-dimer assay as a screening tool to exclude CVT, particularly when MRI or CT venography is not available. Although the reported sensitivity rates are fair at 83 to 100%, larger prospective studies need to be done to further define the role of D-dimer in the evaluation of CVT because several case reports have noted normal D-dimer levels in the setting of documented CVT.[70-74] In general, although a normal D-dimer level does not exclude the diagnosis of CVT, it does appear to make this diagnosis much less likely, particularly in a patient with symptoms of less than 2 weeks in duration.

Differential Considerations

Considerations in the differential diagnosis of CVT include the conditions that cause patients to present with the new onset of neurologic deficits, alteration in consciousness, or severe headache. A diagnosis of CVT should be considered in a patient with such symptoms when the etiology is unclear, particularly when there is the possibility of a hypercoagulable state and when the head CT scan is normal in appearance or shows subtle signs of CVT.

Management

CVT is a relatively rare disease, and controlled studies evaluating its treatment are lacking. Current therapeutic consensus strongly recommends systemic anticoagulation with low-molecular-weight heparin (LMWH) or unfractionated heparin to prevent further clot formation and to promote recanalization, even in patients with intracranial hemorrhage on initial imaging.[59,60,74,75] In one placebo-controlled randomized trial comprising only 20 patients, anticoagulation with unfractionated heparin demonstrated benefit, even in patients with evidence of intracranial hemorrhage on the pretreatment CT scan.[76] A registry comparing outcomes of patients treated with unfractionated heparin compared with LMWH found more benefit in the LMWH group, although the effect was modest.[77] Two large observational trials also showed improvement in modified Rankin scale at follow-up in the anticoagulated groups, although the trials were not randomized.[57,61] Despite a paucity of randomized controlled trials, expert opinion favors anticoagulation in all groups unless another contraindication is present.[78]

Catheter-based intervention with thrombolysis has been attempted in multiple case series with use of either urokinase or tissue plasminogen activator. Thrombolysis was shown to be relatively safe and relatively successful in very small case series.[75] In one nonrandomized study of 40 patients, 20 received systemic heparin and 20 received catheter-based infusion of urokinase followed by systemic heparin. Despite initially worse neurologic function in the thrombolysis group, a significant difference in neurologic function favoring thrombolysis was observed at discharge.[79] This promising therapy is typically considered only for patients with symptoms of decreased level of consciousness, elevated ICP, or rapid deterioration on neurologic examination.

Disposition

All patients with suspected CVT should be admitted to a unit capable of providing a high level of care with neurologic consultation. Patients should be anticoagulated if no contraindication exists, and catheter-based thrombolysis should be considered in patients with depressed mental status or focal findings on neurologic examination.

MULTIPLE SCLEROSIS

Perspective

Multiple sclerosis (MS) is an inflammatory disease that affects the central nervous system (CNS). Although the exact etiology remains uncertain, the pathologic manifestation of this inflammatory disease is a demyelination of discrete regions (plaques) within the CNS with a relative sparing of axons. The clinical picture is highly variable but is classically characterized by episodes of neurologic dysfunction that evolve in days and resolve during weeks.

MS has an overall prevalence in the United States of 0.1%. The peak age at onset is 25 to 30 years; women are slightly younger than men at onset. The incidence in women exceeds that of men by a ratio of 1.8 : 1. The worldwide prevalence is greatest in the United Kingdom, Scandinavia, and North America. Epidemiologic studies indicate that both genetic and environmental factors are associated with an increased incidence of this disease. MS has a 30% concordance rate between monozygotic twins, and 20% of patients with MS have at least one affected relative. MS is more common in temperate climates. It is rare between 23 degrees north and south latitudes but has a rising incidence above and below 50 degrees north and south latitudes, respectively. Although no exact environmental factor has been identified, if a person emigrates from an area of high prevalence to an area of low prevalence before the age of 20 years, the risk is diminished. MS is rare in Africans and Asians, but African Americans have a higher incidence than their relatives who remain in Africa.[80] In addition, reports of clusters or mini-epidemics support environmental factors. Thus, an environmental cause superimposed on genetic susceptibility appears to be a likely etiologic scenario.[81,82]

Principles of Disease

MS is considered to be an organ-specific autoimmune disease. One theory proposes that genetic factors interact with an environmental trigger or infection to establish pathologically autoreactive T cells in the CNS. After a long and variable latency period (typically 10 to 20 years), a systemic trigger, such as a viral infection or superantigen, activates these T cells. The activated T cells, on reexposure to the autoantigen, initiate the inflammatory response. This sets off a complex immunologic cascade that leads to the demyelination characteristic of MS. This demyelination process releases CNS antigens that are hypothesized to initiate further episodes of autoimmune-induced inflammation. The mechanisms underlying this autoimmunity in MS are unknown.[83]

Clinical Features

The clinical picture in MS is one of marked heterogeneity. The classic clinical syndrome consists of recurring episodes of neurologic symptoms that rapidly evolve during days and slowly resolve. Variability occurs in age at onset, location of CNS lesions, frequency and severity of relapses, and degree and time course of progression.

The clinical features of MS can be divided into areas of specific CNS impairment: cognition; cranial nerves; motor pathways;

www.ketabpezeshki.com 66485457-66963820

sensory pathways; cerebellar pathways; and bowel, bladder, and sexual dysfunction.[80]

Patients with MS have frequent complaints of poor memory, distractibility, and decreased capacity for sustained mental effort. Formal neuropsychological testing suggests that cognitive involvement is common and underreported. Specifically, neuropsychological testing has shown that 43 to 65% of patients with MS have some degree of cognitive impairment.[84,85] Of note, a correlation has been found between the MRI-based total lesion load and presence of cognitive impairment.[86]

Cranial nerve dysfunction is common in MS. The most common associated cranial nerve abnormality is *optic neuritis,* a unilateral syndrome characterized by pain in the eye and a variable degree of visual loss affecting primarily central vision. Within 2 years of an attack of optic neuritis, the risk of MS is approximately 20%, and within 15 years, it is approximately 45 to 80%.[87,88] Optic neuritis often is the first symptom of MS.[89,90]

As a result of lesions in the vestibulo-ocular connections, the oculomotor pathways also may be affected. The deficit may be manifested as diplopia or nystagmus. The nystagmus may be severe enough that the patient may complain of oscillopsia (a subjective oscillation of objects in the visual field). Cranial nerve impairment also may include impairment of facial sensation, which is relatively common. Unilateral facial paresis also may occur. In addition, the occurrence of trigeminal neuralgia in a young person may be an early sign of MS.

Motor pathways also are commonly involved. Specifically, corticospinal tract dysfunction is common in patients with MS. Paraparesis or paraplegia occurs with greater frequency than upper extremity lesions owing to the common occurrence of lesions in the motor tracts of the spinal cord. In patients with significant motor weakness, spasms of the legs and trunk may occur on attempts to stand from a seated position. This dysfunction is manifested on physical examination as spasticity that typically is worse in the legs than in the arms. The deep tendon reflexes are markedly exaggerated, and sustained clonus may be demonstrated. Although these symptoms frequently are bilateral, they generally are asymmetrical.[80]

Sensory manifestations are a frequent initial feature of MS and will be present in nearly all patients at some point during the course of the disease. Sensory symptoms are commonly described as numbness, tingling, "pins and needles" paresthesias, coldness, or a sensation of swelling of the limbs or trunk.[80]

Impairment of the cerebellar pathway results in significant gait imbalance, difficulty with coordinated actions, and dysarthria. Physical examination reveals the typical features of cerebellar dysfunction, including dysmetria, dysdiadochokinesis (an impairment of rapid alternating movements), breakdown in the ability to perform complex movements, intention tremor in the limbs and head, truncal ataxia, and dysarthria.[80]

Impairment of bowel, bladder, and sexual function also is common. The extent of sphincter and sexual dysfunction usually parallels the motor impairment in the lower extremities. Urinary frequency may progress to urinary incontinence as the disease advances. An atonic bladder may develop, which empties by simple overflow and often is associated with the loss of perception of bladder fullness and with anal and genital hypoesthesia. Constipation becomes common in time, and almost all patients with paraplegia require special measures to maintain effective bowel habits. Sexual dysfunction, although frequently overlooked, is common in MS. Approximately 50% of patients become completely sexually inactive as a result of this disease.[80]

Diagnostic Strategies

Although no laboratory tests are diagnostic for MS, one clinical feature remains unique to this disease: *Uhthoff's phenomenon,* temporary worsening of current or preexisting signs or symptoms of MS secondary to small increases in the patient's body temperature. Accordingly, exercise, a hot bath, exposure to a warm environment, or fever can bring about Uhthoff's phenomenon. This phenomenon reflects subclinical demyelination or preexisting injury to nerves without obvious significant clinical involvement before heat exposure or temperature elevation.[80]

MS is described as a relapsing-remitting disorder with symptoms that fluctuate over time. Therefore, the clinical diagnosis rests on occurrence of at least two clinical episodes with different neurologic symptoms at different times.

Findings on CSF analysis are abnormal in 90% of the cases. Fifty percent of patients will have pleocytosis, with more than five lymphocytes per high-power field in the CSF. Approximately 70% of patients will have an elevated gamma globulin level, with immunoglobulin G (IgG) ranging from 10 to 30% of the CSF total protein. Electrophoresis of the CSF demonstrates oligoclonal bands of IgG in 85 to 95% of patients who carry a diagnosis of MS; however, oligoclonal bands of IgG also are seen with neurosyphilis, fungal meningitis, and other CNS infections. Lumbar puncture is recommended for patients with suspected MS, but mass lesions and elevated ICP should be ruled out before lumbar puncture is attempted.[91]

The initial imaging test to aid in the diagnosis of MS is gadolinium-enhanced MRI. MRI is a sensitive test for the detection of lesions consistent with MS and also is useful to assess disease severity.[92] The lesions of MS typically appear hyperintense, or bright white, on T2-weighted or fluid-attenuated inversion recovery (FLAIR) MRI studies. Lesions usually are multiple and commonly are found in the periventricular white matter.[93] In patients with an initial neurologic event consistent with CNS demyelination and an MRI cranial study showing multiple white matter lesions, the 5-year risk for development of MS is 60%. Patients with similar clinical syndromes and a normal MRI appearance have less than a 5% 5-year risk.[94]

Differential Considerations

Other diseases that affect the CNS white matter may be clinically and radiographically similar to MS. Considerable care must be taken to exclude these disease processes before a diagnosis is made. These include CNS tumors (especially lymphomas and gliomas), spinal cord compression, vasculitides, Behçet's disease, neurosarcoidosis, postinfectious and postvaccinal encephalomyelitis, human immunodeficiency virus (HIV) encephalopathy, Lyme disease, and vitamin B_{12} deficiency.

Management

Management of patients with MS has essentially three aspects: (1) therapies aimed at halting the progression of the disease, (2) treatment of acute exacerbations, and (3) therapies designed to modify complications.

Therapies aimed at halting disease progress are based primarily on the use of either interferon-β or glatiramer acetate. The interferons are a group of natural compounds with antiviral and immunomodulatory actions used in therapy for MS. Side effects of the agents interferon-β1a and interferon-β1b include influenza-like symptoms, depression, anxiety, and confusion. In one study, 560 patients with MS were randomly assigned to receive subcutaneous interferon-β1a or placebo (n = 187) three times a week for 2 years.[95] The relapse rate was significantly lower at 1 and 2 years with interferon-β1a than with placebo. The time to first relapse was prolonged significantly and the accumulation of brain lesions on MRI was lower in the treatment group than in the placebo group. The investigators concluded that subcutaneous interferon-β1a is a well-tolerated and effective treatment of

www.ketabpezeshki.com 66485457-66963820

relapsing-remitting MS in terms of relapse rate, defined disability, and all MRI outcome measures.[81] Interferon-β also has been shown to retard progression to clinically definite MS and to decrease the total number of brain lesions seen on subsequent MRI studies in patients who have their first demyelinating episode with MRI abnormalities at initial presentation.[96-99] This finding highlights the importance of early evaluation and treatment.

Glatiramer acetate also has successfully been used in the treatment of MS. This agent is a mixture of synthetic polypeptides designed to mimic myelin basic protein. The mechanism of action by which glatiramer acetate exerts its effect is unknown, but it is thought to modify the immune processes responsible for the pathogenesis of MS. In one study, 251 patients with relapsing-remitting MS were randomized to receive daily subcutaneous injections of glatiramer acetate (previously called copolymer 1) or placebo for 24 months. Patients receiving glatiramer acetate experienced significantly fewer relapses and were more likely to demonstrate neurologic improvement, whereas those receiving placebo were more likely to worsen. This drug generally is well tolerated.[100] Glatiramer acetate has also been shown to slow the progression to clinically definite MS after a first clinical demyelinating episode.[101]

Current recommendations for management of relapsing-remitting MS are to initiate treatment with interferon-β or glatiramer acetate. Such regimens have been demonstrated to decrease the volume of plaques seen on MRI and to diminish relapses.[83] The use of newer disease-modifying agents, such as fingolimod, cladribine, and natalizumab, has shown promise in clinical trials, but each has significant side effect profiles, and appropriate patient selection is still underway.[102-107] At this point, each of these agents is considered second line for severe or refractory patients.

Acute exacerbations of MS also should be targets for therapy. Although most such episodes will resolve without therapy, steroids have been demonstrated to diminish the duration of acute exacerbations. More than 85% of patients with relapsing-remitting MS show improvement with intravenous methylprednisolone. Intravenous steroids have been shown in controlled trials to speed the recovery from the visual loss of optic neuritis compared with placebo. In addition, when patients with acute optic neuritis are treated with high-dose intravenous steroids, the 2-year rate of development of MS is reduced, although this effect diminishes over time.[88,108] Of interest, oral prednisone was not found to be helpful in the optic neuritis trials and was associated with a potential increase in the number of optic neuritis episodes.

The current standard therapy for an acute exacerbation in MS is intravenous methylprednisolone. A typical intravenous dose is 250 to 500 mg every 12 hours for 3 to 7 days. Whether this should be followed by an oral prednisolone taper remains controversial. Potential adverse effects of methylprednisolone therapy include fluid retention, gastrointestinal hemorrhage, anxiety, psychosis, infection, and osteoporosis.

Several therapies directed toward the complications of MS may be helpful. The associated spasticity generally is treated with baclofen. This is a highly effective therapy aimed at reducing the painful flexor and extensor spasms. A major side effect is drowsiness, which generally diminishes with continued use. Higher-dose therapy can cause confusion, especially in the setting of baseline cognitive impairment. For patients with intractable spasticity, baclofen is available for intrathecal administration by either bolus therapy or continuous implanted pump therapy. Additional therapeutic agents for control of spasticity include tizanidine, diazepam, and dantrolene.

The tremor and ataxia associated with MS occasionally are treated with propranolol, diazepam, or clonazepam. The results of these therapies, however, generally are unsatisfactory. Pain often is associated with MS and affects the shoulders, pelvic girdle, and face. The facial pain may be indistinguishable from that of trigeminal neuralgia. Treatment options include carbamazepine, baclofen, and tricyclic antidepressants. Fatigue, which is common, may be ameliorated with amantadine. This agent produces partial relief for a minority of patients. In controlled studies, the effect is only slightly better than placebo.[83]

Disposition

Patients with a history of MS who seek treatment for significant symptoms must first be evaluated to rule out other, non–MS-related pathologic processes. Also, other systemic illnesses, especially infections, which can worsen the symptoms of MS, should be excluded. If the problem is thought to be an exacerbation of MS, most patients will require hospital admission for intravenous steroid therapy. An alternative to hospitalization may be to initiate intravenous steroids in the ED and to arrange for a next-day follow-up visit with the primary care physician or neurologist if outpatient intravenous steroid administration is an option.

Patients with the new onset of symptoms suggestive of MS should be admitted or referred to a neurologist because early treatment has been shown to significantly decrease progression of the disease.

KEY CONCEPTS

Trigeminal Neuralgia

- Patients with unilateral, intermittent, lancinating facial pain without abnormalities on physical examination are likely to have trigeminal neuralgia.
- Carbamazepine is the first-line agent for medical treatment.
- Patients who do not tolerate or whose pain is refractory to medical management may be candidates for microvascular decompression or ablation.

Facial Nerve Paralysis

- Patients with Bell's palsy should be treated early in the course with corticosteroids, and antiviral medication is warranted in patients with severe loss of function.
- Slowly progressive or recurrent facial paralysis is suggestive of a neoplasm. Recurrent unilateral paralysis may occur with Bell's palsy but frequently (30%) is seen in patients with tumor.
- Simultaneous bilateral facial paralysis is suggestive of Lyme disease, especially in endemic regions.
- Patients who have facial muscle paresis with intact forehead movement should be considered to have a central (upper motor neuron) lesion until the diagnostic investigation proves otherwise.

Vestibular Schwannoma

- The onset of unilateral auditory symptoms, especially sensorineural hearing loss, requires evaluation and referral to an ear, nose, and throat specialist.
- Neurologic symptoms of lower cranial nerve dysfunction, ataxia, or raised ICP may be caused by a benign tumor of the cerebellopontine angle.

Diabetic Cranial Mononeuropathy

- Diabetic neuropathy is a diagnosis of exclusion because no definitive diagnostic testing is available.
- Both ischemic and hemorrhagic brainstem lesions must be ruled out in the case of an acute ophthalmoplegia.
- Extraocular mononeuropathy is sufficiently common in patients with diabetes mellitus that its occurrence in isolation warrants evaluation of the patient for previously undiagnosed diabetes.

Cerebral Venous Thrombosis

- The differential diagnosis for CVT includes other conditions that present with new-onset neurologic deficits, alteration in

www.ketabpezeshki.com 66485457-66963820

consciousness, or severe headache. CVT is more likely to be present in such patients when the etiology is unclear, the patient is thought to have a hypercoagulable state, and the head CT is normal in appearance or shows subtle signs of CVT.

- Non–contrast-enhanced CT scanning is not adequate to rule out CVT. MRI with MRV is recommended, although multidetector row CT venography is an acceptable alternative.
- Treatment of most patients with CVT includes systemic anticoagulation, even in the setting of hemorrhagic cerebral infarcts, unless another contraindication exists.

Multiple Sclerosis

- Any patient with a long-term illness, such as MS, must be evaluated to rule out pathologic processes not related to that illness before an exacerbation of the illness can be assumed to be the cause of any problems experienced by the patient.
- Therapy for patients with MS will require consultation with the patient's primary care provider or neurologist to provide consistent disease management.
- Intravenous methylprednisolone effectively promotes earlier resolution of recurrences.
- Intravenous methylprednisolone has been shown to speed the recovery from vision loss from optic neuritis.

Chapter 106

Spinal Cord Disorders

Andrew D. Perron and J. Stephen Huff

PERSPECTIVE

Spinal cord disorders encompass a wide range of pathologic entities and affect all age groups. Some spinal cord disorders may have catastrophic outcomes if they are not recognized early in the clinical course. The ultimate neurologic outcome with many of these disorders may depend on expeditious recognition in the emergency department (ED), with appropriate initial investigations, neuroimaging, management, and consultation for definitive therapy. Early presentations of spinal cord syndromes are frequently subtle, and diagnosis may be difficult if not impossible in the early stages of disease. As with many disease processes affecting the nervous system, correct diagnosis and appropriate management require knowledge of the anatomic organization of the spinal cord and skill in taking the history and in performing the neurologic examination.

This chapter generally is concerned with nontraumatic processes affecting the spinal cord and its vascular supply as well as processes compressing the spinal cord. Spinal cord trauma is discussed in Chapter 43.

PRINCIPLES OF DISEASE

Anatomy

In adults, the spinal cord is approximately 40 cm long and extends from the foramen magnum, where it is continuous with the medulla oblongata, to the body of the first or second lumbar vertebra. Like the brain, the spinal cord is covered by three meningeal layers: the inner pial layer, the arachnoid, and the outer dural layer. At its lower end, the spinal cord tapers into the conus medullaris, where several segmental levels are represented in a small area. The lumbar and sacral nerve roots form the cauda equina as they descend caudally in the thecal sac before exiting the spinal canal at the respective foramina. The non-neural filum terminale runs from the tip of the conus and inserts into the dura at the level of the second sacral vertebra.

Two symmetrical enlargements of the spinal cord contain the segments that innervate the limbs. The *cervical enlargement* (cord level C5 to T1) gives rise to the brachial plexus and subsequently to the peripheral nerves of the upper extremity. The *lumbar enlargement* (L2 to S3) gives rise to the lumbosacral plexus and peripheral nerves of the lower extremity. The space surrounding the spinal cord within the spinal canal is reduced in the area of the enlargements, potentially leaving the cord more vulnerable to compression in these regions. At each segmental level, anterior (ventral) and posterior (dorsal) roots arise from rootlets along the anterolateral and posterolateral surfaces of the cord. At each level, the anterior root conveys the outflow of the motor neurons in the anterior horn of the spinal cord, and the posterior root contains sensory neurons and fibers that convey sensory inflow.

The arterial supply of the spinal cord is derived primarily from two sources. The single anterior spinal artery arises from the paired vertebral arteries. This anterior spinal artery runs the entire length of the cord in the midline anterior median sulcus and supplies roughly the anterior two thirds of the spinal cord. Blood supply to the posterior third of the spinal cord is derived from the smaller paired posterior spinal arteries. The anterior and the posterior spinal arteries receive segmental contributions from radicular arteries, the largest being the radicular artery of Adamkiewicz, which typically originates from the aorta between T8 and L4. The venous drainage of the cord largely parallels the arterial supply.

The internal anatomy of the spinal cord is divided into central gray matter, which contains cell bodies and their processes, and surrounding white matter, where the ascending and descending myelinated fiber tracts are located. These fiber tracts are organized into discrete bundles; the ascending tracts convey sensory information, and the descending tracts convey the efferent motor impulses and visceral innervation.

For clinical purposes, neuroanatomy of the spinal cord may be greatly simplified, as depicted in Figure 106-1. Major ascending sensory tracts are represented on the right side of the figure, with motor tracts on the left side. The posterior columns carry afferent ascending proprioceptive and vibratory information on the ipsilateral side of the cord to the area stimulated; decussation of these fibers occurs in the medulla so that contralateral cortical representation is consistent. The lateral spinothalamic tract conveys afferent information about pain and temperature in a portion of the lateral column of white matter. (Tracts are named with the point of origin first; the spinothalamic tract, for example, arises in the spinal cord and travels to the thalamus.) The tract is laminated so that sacral fibers are represented most laterally. Crossing of fibers from this tract occurs near the level of entry of the spinal nerve; a cord lesion affecting only one lateral spinothalamic tract results in decreased or absent pain and temperature perception below the level of injury on the contralateral side of the body.

For clinical purposes, the major descending motor tract is represented in the lateral corticospinal tract (which, as the name implies, originates in the cortex and descends to the spinal cord). This tract also is anatomically organized, with efferent motor axons to the cervical area located medially and the sacral efferent axons located laterally. Decussation of this descending tract occurs in the medulla. The cell bodies of the lower motor neurons (anterior horn cells) are in the ventral (anterior) portion of the gray matter of the spinal cord.

CLASSIFICATION OF SPINAL CORD SYNDROMES

The anatomic organization of the spinal cord lends itself to a corresponding anatomic-pathophysiologic classification of cord dysfunction. Any of the different anatomic syndromes may be the final clinical picture of a variety of clinical processes. The syndromes frequently exist in partial or incomplete forms, adding to the diagnostic difficulty.

Complete (Transverse) Spinal Cord Syndrome

Complete spinal cord lesions may be manifested as either acute or subacute pathologic processes. A *complete* spinal cord lesion is defined as a total loss of sensory, autonomic, and voluntary motor innervation distal to the spinal cord level of injury. Reflex responses mediated at the spinal level, such as muscle stretch (deep tendon) reflexes, may persist, although they also may be absent or abnormal. Autonomic dysfunction may be manifested acutely with hypotension (neurogenic shock) or priapism. The most common cause of the complete transverse cord syndrome is trauma, although this anatomic syndrome is nonspecific as to etiology.[1,2] Other causes of acute complete cord syndrome include infarction, hemorrhage, and entities causing extrinsic compression. In patients with acute complete transverse syndromes that persist for more than 24 hours, functional recovery does not occur in 99%.[3,4] Any evidence of preserved cord function below the level of injury denotes a partial rather than a complete lesion. Signs such as persistent perineal sensation (sacral sparing), reflex rectal sphincter tone or voluntary rectal sphincter contraction, and even slight voluntary toe movement suggest a partial cord lesion, which usually carries a better prognosis than a complete lesion.[1]

Spinal shock refers to the loss of muscle tone and reflexes with complete cord syndrome during the acute phase of injury. The intensity of the spinal shock increases with affected spinal cord level.[5] Spinal shock typically lasts less than 24 hours but has been reported occasionally to last days to weeks.[5,6] A marker of spinal shock is loss of the bulbocavernosus reflex, which is a normal cord-mediated reflex that may be preserved in complete cord lesions. The bulbocavernosus reflex involves involuntary reflex contraction of the anal sphincter in response to a squeeze of the glans penis or a tug on the Foley catheter. The termination of the spinal shock phase of injury is heralded by the return of the bulbocavernosus reflex; increased muscle tone and hyperreflexia follow later.[1,5,6]

Incomplete Spinal Cord Lesions

Incomplete spinal lesions are characterized by preservation of function of various portions of the spinal cord. Of all incomplete spinal lesions, most can be classified generally as one of three clinical syndromes: central cord syndrome, Brown-Séquard syndrome, or anterior cord syndrome (Table 106-1).

Central Cord Syndrome

Central cord syndrome, first described by Schneider and colleagues in 1954, is the most prevalent of the partial cord syndromes.[7,8] Because of the anatomic organization of the spinal cord, a central cord injury is characterized by bilateral motor paresis; upper extremities are affected to a greater degree than lower extremities, and distal muscle groups are affected to a greater degree than proximal muscle groups. Sensory impairment and bladder dysfunction are variable features. At times, burning dysesthesias in the upper extremities may be the dominant feature.[9] Central cord injury affects the central gray matter and the central portions of the corticospinal and spinothalamic tracts. It is caused most often by a hyperextension injury; the postulated mechanism is squeezing or pinching of the spinal cord anteriorly and posteriorly by inward bulging of the ligamentum flavum. The most common cause of such injuries is a fall, followed in frequency by a motor vehicle crash.[7,8] The result is contusion to the spinal cord, with the central portion being most affected. This injury often occurs in elders with degenerative arthritis and spinal stenosis in the cervical area but may affect any patient with cervical canal narrowing of any etiology (e.g., congenital narrow canal as seen in achondroplasia or canal narrowing from disk protrusion or tumor). The prognosis with central cord syndrome depends on the degree of injury at presentation and the patient's age.[10,11] In patients younger than 50 years, more than 80% regain bladder continence, and approximately 90% return to ambulatory status. In patients older than 50 years, only 30% regain bladder function, and approximately 50% regain the ability to ambulate.[11]

Brown-Séquard Syndrome

Brown-Séquard syndrome, first described in 1846 by the one physician for whom it is named,[12] is the result of an anatomic or functional hemisection of the spinal cord. Usually associated with penetrating injuries,[13] Brown-Séquard syndrome also may be seen with compressive or intrinsic lesions. The syndrome has been reported in association with spinal cord tumors, spinal epidural hematoma, vascular malformations, cervical spondylosis, degenerative disk disease, herpes zoster myelitis, and radiation injury and as a complication of spinal instrumentation.[13,14] The syndrome in its pure form is characterized by ipsilateral loss of motor function and proprioception or vibration, with contralateral loss of pain and temperature sensation below the spinal cord level of injury. Because fibers associated with the lateral spinothalamic tract ascend or descend one or two spinal cord segments before crossing to the contralateral side, ipsilateral anesthesia (pain and temperature modalities) may be noted one or two segments above the lesion, although this observation is variable. Most patients with Brown-Séquard syndrome incur only partial sensory and motor impairment, and the classic pattern is not seen.[11,13,15] Brown-Séquard syndrome carries the best prognosis of any of the incomplete spinal cord syndromes. Fully 80 to 90% of patients with Brown-Séquard syndrome regain bowel and bladder func-

Table 106-1 Spinal Cord Syndromes

SYNDROME	SENSORY	MOTOR	SPHINCTER INVOLVEMENT
 Central cord syndrome	Variable	Upper extremity weakness, distal > proximal	Variable
 Brown-Séquard syndrome	Ipsilateral position and vibration sense loss Contralateral pain and temperature sensation loss	Motor loss ipsilateral to cord lesion	Variable
 Anterior cord syndrome	Loss of pin and touch sensation Vibration, position sense preserved	Motor loss or weakness below cord level	Variable
 Transverse cord syndrome—complete	Loss of sensation below level of cord injury	Loss of voluntary motor function below cord level	Sphincter control lost
Conus medullaris syndrome	Saddle anesthesia may be present, or sensory loss may range from patchy to complete transverse pattern	Weakness may be of upper motor neuron type	Sphincter control impaired
Cauda equina syndrome	Saddle anesthesia may be present, or sensory loss may range from patchy to complete transverse pattern	Weakness may be of lower motor neuron type	Sphincter control impaired

tion, 75% regain ambulatory status, and 70% become independent in their activities of daily living.[11]

Anterior Cord Syndrome

Anterior cord syndrome is characterized by loss of motor function, pinprick, and light touch below the level of the lesion with preservation of posterior column modalities, including some touch, position, or vibratory sensation. Although most reported cases of anterior spinal syndrome follow aortic surgery,[16] the syndrome also may occur after severe hypotension, infection, myocardial infarction, vasospasm from drug reaction, and aortic angiography.[17] The anatomic lesion may be caused by a cervical hyperflexion injury resulting in a cord contusion or by protrusion of bone fragments or herniated cervical disk material into the spinal canal. Rarely, it is produced by laceration or thrombosis of the anterior spinal artery or a major radicular feeding vessel.[11] Patients present with characteristic mixed motor and sensory neurologic findings as noted before. Functional recovery varies; most improvement occurs during the first 24 hours, but little improvement is expected thereafter.[4] Although anterior cord lesions from ischemia usually are incomplete, patients without motor function at 30 days have little or no likelihood of regaining any motor function by 1 year.[16,18] Overall, only 10 to 20% of patients with this entity regain some muscle function, and even in this group, there is little power or coordination.[11]

Conus Medullaris and Cauda Equina Syndromes

The separation of conus medullaris and cauda equina lesions in clinical practice is difficult because the clinical features of the

www.ketabpezeshki.com 66485457-66963820

disorders overlap. In addition, a combined lesion may occur that masks clear clinical symptoms or signs of either an upper or a lower motor neuron type of injury. The conus medullaris is the terminal end of the spinal cord, located at approximately the L1 level in adults. The conus medullaris syndrome may involve disturbances of urination (usually from a denervated, autonomic bladder that is manifested clinically with overflow incontinence) and sphincter impairment or sexual dysfunction. Sensory involvement may affect the sacral and coccygeal segments, resulting in saddle anesthesia. Pure lesions of the conus medullaris are rare.[19] Upper motor neuron signs, such as increased motor tone and abnormal reflexes, may be present, but their absence does not exclude the syndrome. The conus medullaris syndrome can be caused by central disk herniation, neoplasm, trauma, or vascular insufficiency. Because the conus is such a small structure, with lumbar and sacral segments represented in a small area, a lesion usually causes bilateral symptoms. This finding may help distinguish lesions of the conus from lesions of the cauda equina, which often are unilateral.[19]

The *cauda equina* (Latin for "horse's tail") is the name given to the lumbar and sacral nerve roots that continue on within the dural sac caudal to the conus medullaris. Not a true "cord syndrome," cauda equina syndrome represents dysfunction at the level of nerve roots, but the anatomic clustering of nerve roots within the lumbar dural sac allows injury to several nerve roots to occur simultaneously. The etiologic lesion in the cauda equina syndrome usually is a midline rupture of an intervertebral disk, most commonly at the L4-5 level. Tumors and other compressive masses also may cause the syndrome. As in the conus medullaris syndrome, patients generally present with progressive symptoms of fecal or urinary incontinence, impotence, distal motor weakness, and sensory loss in a saddle distribution. Muscle stretch reflexes also may be reduced. Urinary retention is the most consistent finding, with a sensitivity of 90%.[20] Low back pain may or may not be present.

CLINICAL FEATURES

History

Weakness, sensory abnormalities, and autonomic dysfunction are the cardinal manifestations of spinal cord dysfunction. The tempo and degree of impairment often reflect the disease process. Past medical history is vital because a history of coagulopathy or other systemic processes may be elicited. A history of cancer should suggest the possibility of metastatic disease. Recent trauma raises the possibility of vertebral fracture or disk protrusion.

Physical Examination

The physical examination pertinent to spinal cord dysfunction involves testing in three areas: (1) motor function, (2) sensory function, and (3) reflexes. Each component is best tested with the anatomic organization of the spinal cord in mind to help determine the level of the spinal cord dysfunction.

Motor Function

Testing of motor function encompasses examination of muscle bulk, tone, and strength. Muscle bulk is easily examined in large motor groups, such as the thigh or calf muscles, the biceps, and the triceps. Inspection of the intrinsic hand muscles also may be helpful for determination of muscle bulk; wasting may be evident as hollowed or recessed regions of the hand. Decreased mass, asymmetry, or fasciculations should be noted. Tone is tested with repeated passive knee, elbow, or wrist flexion, with the examiner feeling for abnormally increased or decreased resistance. Rapid pronation-supination of the forearm is another useful method to assess tone. Increased tone may indicate spasticity or an upper motor neuron lesion, whereas decreased tone corresponds with lower motor neuron, motor endplate, or muscle problems. Finally, motor strength is graded in the upper and the lower extremities. Motor grading for the neurologic examination is relatively straightforward. Note that a tremendous gradient of strength is within the fourth grade of the scale. Scored on a scale of 0 to 5, neuromuscular functioning is graded as follows:

0. No firing of the muscle is present.
1. The muscle fires but is unable to move the intended part.
2. The muscle is able to move the intended part with gravity eliminated.
3. The muscle is able to move the intended part against gravity.
4. The muscle is able to move the intended part, but not at full strength.
5. Full muscle strength is present.

A rectal examination is performed to assess voluntary sphincter contraction, resting tone, and, as described previously, the bulbocavernosus reflex. Although it is not commonly thought of as a physical examination maneuver, a post-void residual urine volume may be important for assessment of bladder function. A post-void residual volume of more than 100 to 200 mL in a patient without prior voiding difficulty might suggest bladder dysfunction of neurologic cause.

Sensory Function

Sensory testing requires a cooperative patient and an attentive examiner. The spinal cord–related modalities that may be clinically useful include testing for pinprick and light touch (contralateral lateral spinothalamic tract) and proprioception (ipsilateral posterior column). Assessment of the patient's response to pinprick, light touch, and proprioception in all four extremities is necessary if a neurologic injury is suspected. Testing of sacral dermatomes is an important part of the examination in some patients. As previously noted, sacral sparing is an important finding indicating that spinal cord dysfunction may be incomplete. The sensory fibers from sacral dermatomes are more peripherally located in the ascending fiber bundles; central or partial cord lesions may ablate sensation in the extremities yet allow some perception of sensation in the sacral area.

Reflexes

Muscle stretch (deep tendon) reflexes may be tested rapidly at the bedside. Responses are graded on a scale of 0 to 4+, with 2 being normal. Hyperactive reflexes suggest upper motor neuron disease (affecting the neurons or their outflow from the brain or spinal cord), as do sustained clonus and Babinski's sign. The absence of these reflex changes does not constitute evidence that a myelopathy is not present. In fact, one small series noted a low incidence of extensor plantar responses as well as a lack of hyperreflexia in patients presenting to the ED with acute or progressive cord compression or myelopathies.[21] Reflexes also may be diminished or absent when sensation is lost or when spinal shock is present. Diseases of muscles or neuromuscular junctions also may decrease reflexes. In acute cord injury, reflexes may be diminished in the acute phase. The bulbocavernosus reflex may be helpful in this assessment.

DIAGNOSTIC STRATEGIES

Historical or physical examination findings that suggest spinal cord dysfunction prompt further investigations. The basic strategy is to detect or to exclude extrinsic compressive lesions or other potentially treatable entities. Magnetic resonance imaging (MRI)

www.ketabpezeshki.com 66485457-66963820

Table 106-2 Clinical Characteristics of Neuromuscular Diseases

	HISTORY	STRENGTH	DTR	SENSATION	WASTING
Myelopathy	Trauma, infection, cancer	Normal to decreased	Increased	Normal to decreased	No (yes if chronic)
Motor neuron disease (ALS)	Progressive difficulty with swallowing, speaking, walking	Decreased	Increased	Normal	Yes
Neuropathy	Recent infection Ascending weakness	Normal or decreased Distal > proximal	Decreased	Decreased	Yes

Myopathy	Thyroid disease Previous similar episodes	Decreased Proximal > distal	Normal	Normal	Yes

ALS, amyotrophic lateral sclerosis; *DTR,* deep tendon reflex.

has changed the diagnostic approach to patients with suspected spinal cord dysfunction. Plain radiographs and computed tomography (CT) scans may show bone and some soft tissue abnormalities. Conventional radiographs and CT scans are required in patients with trauma or suspected bone involvement by tumor or degenerative processes, but MRI shows many of these abnormalities and defines the spinal cord as well as the soft tissue structures associated with it. Tissue damage patterns within the cord, such as hemorrhage and edema, also may be detected with MRI. CT myelography may be able to answer some of these questions in patients in whom implanted metal precludes MRI but generally does not yield the same level of detail. After imaging studies exclude compressive lesions or other masses affecting the spinal cord, the possibility of inflammatory or demyelinating disorders remains. Lumbar puncture may be useful in diagnosis by revealing an inflammatory cerebrospinal fluid (CSF) formula.

DIFFERENTIAL CONSIDERATIONS

The prime principle in management of spinal cord dysfunction is to consider and exclude potentially treatable clinical conditions. The clinical assessment of spinal cord dysfunction is limited to detection of weakness, sensory alterations, sphincter dysfunction, and perhaps reflex abnormalities. There may be pain in the back, depending on the pathologic process, but generally it is not helpful in formulating a list of considerations for the differential diagnosis. Because potential functional loss and impact on quality of life are great, the detection of a process for which some intervention is possible assumes great importance. A likely diagnosis of spinal cord infarction may be entertained, but the pursuit of a treatable process, such as spinal cord compression from an epidural hematoma, should be seriously considered.[22] This discovery process may involve specialty consultation or studies that may not be readily available in all settings, such as MRI. As a general rule, liberal use of consultation and imaging is recommended when the possibility of spinal cord dysfunction is considered. The history may suggest a specific cause and will guide the tempo of investigation. The caveat is that spinal cord diseases may mimic many other disease processes, and neither the history nor physical examination may allow diagnosis until appreciable neurologic dysfunction has developed.

The picture of a *complete* transverse spinal cord syndrome with paraplegia, sensory loss at a clear anatomic level, and sphincter dysfunction cannot be fully simulated by other anatomic lesions. *Incomplete* or evolving spinal cord syndromes may be imitated by other disease processes. It is always prudent to focus the differential diagnosis on anatomic considerations—the classic "where is the lesion?" approach (Table 106-2). Progressive lower extremity weakness and sensory alteration may represent cord dysfunction but could reflect an intracranial vertex mass with bilateral cortical dysfunction. Ataxia may be a finding in cerebellar disease but also has rarely been reported as an isolated finding with spinal cord compression. Another example is rapidly progressive paralysis in a patient with areflexia and quadriplegia; ascending paralysis (Landry-Guillain-Barré syndrome) at times may mimic an acute cord lesion.

In general, pathologic processes involving the spinal cord may be divided into processes affecting the cord or its blood supply primarily, such as demyelination, infection, or infarction, and processes that compress the cord, most often originating outside the dura (Box 106-1). *Myelitis* is a comprehensive term for spinal cord inflammation with dysfunction, and the potential causes are legion. The clinical presentation is often similar across the variety of entities that may cause cord compression. The tempo of the process may yield a different clinical picture. In chronic compression, muscle wasting and abnormal reflexes may be present, whereas both of these may be lacking in acute compression. A neurologic deficit in concert with back pain strongly suggests a spinal cord lesion causing compression of neural elements, necessitating prompt investigation to identify a specific cause. Atypical presentations for these lesions are the rule, and additional diagnostic studies should be pursued as appropriate.

www.ketabpezeshki.com 66485457-66963820

MANAGEMENT

Just as the clinical manifestations of spinal cord dysfunction are nonspecific with respect to etiology, the treatment of many of the disease entities often is nonspecific. Steroid administration had been traditionally recommended as therapy in spinal cord trauma, although currently this use of steroids has been seriously questioned in the medical literature.[23-26] Steroids have also been used with many nontraumatic causes of cord compression, despite the lack of rigorous clinical studies supporting this use. Radiation treatment is recommended for cord compression by tumor. Surgical consultation for decompression may be considered, although the indications for surgery and timing of surgery are controversial.

A specific diagnosis is needed to guide therapy. Accordingly, involvement of appropriate consultants and discussion of what may be understudied therapies are suggested.

SPECIFIC DISEASE PROCESSES

As noted earlier, spinal cord disorders may be grouped into lesions resulting from processes intrinsic to the cord or vasculature and lesions causing extrinsic compression. The order of the following discussion roughly corresponds with the organization of Box 106-1.

Intrinsic Cord Lesions

Multiple Sclerosis

Principles of Disease. Demyelination denotes a disease process with the prominent feature of partial or complete loss of the myelin surrounding the axons of the central nervous system. Multiple sclerosis (MS) is the most common example of such a process; spinal cord involvement may dominate the clinical picture.[27]

Clinical Features. Central nervous system lesions that are "scattered in time and space" are the hallmark of MS, as described in more detail in Chapter 105. The demyelinated segments do not transmit action potentials normally, resulting in a wide variety of spinal cord–related abnormalities, depending on the location and extent of the demyelination. In addition to patchy motor and sensory deficits, patients with MS may complain of bladder dysfunction or tremor or demonstrate evidence of a transverse partial or complete cord syndrome mimicking a compressive spinal lesion.[27, 28] Spinal cord lesions in MS primarily involve the lateral corticospinal tracts, the posterior columns, and the lateral spinothalamic tracts. Motor system dysfunction is the most frequent manifestation of MS involvement of the spinal cord, usually as a result of lesions in the lateral corticospinal tracts.

The examination of patients with MS often reveals paresis, increased muscle tone, hyperreflexia, clonus, and Babinski's response. Spinal cord involvement also may result in dysautonomias.

Diagnostic Strategies. Spinal MRI is the diagnostic imaging modality of choice because it can exclude cord compression and show lesions suggestive of MS.[28-30] CSF testing for myelin basic protein and oligoclonal bands also is a diagnostic option, but no CSF abnormalities are entirely specific for MS.[31,32] Oligoclonal bands in the CSF may aid in the diagnosis, but they are significant only if they are not present in the serum as well.[31]

Differential Considerations. Considerations in the differential diagnosis include systemic lupus erythematosus, Lyme disease, neurosyphilis, human immunodeficiency virus (HIV) myelopathy, and other disorders.

Management. MS exacerbations may be treated with high-dose methylprednisolone, followed by a tapering dose of prednisone.[28] Consultation and referral to a neurologist usually are indicated. Immunosuppressive therapy in patients with the chronic progressive form of the disease has met with variable success.[27,28] Because numerous disorders can mimic MS, the definitive diagnosis of this disease is usually not made in the ED.[33]

Transverse Myelitis

Principles of Disease. Acute transverse myelitis refers to acute or subacute spinal cord dysfunction characterized by paraplegia, a transverse level of sensory impairment, and sphincter disturbance. It describes a heterogeneous group of inflammatory disease processes that can affect the spinal cord by interruption of the ascending or descending pathways in the spinal cord.[34] It is relatively rare, with a reported annual incidence of 1 case per 1.3 million population. The presentation may be mimicked by compressive lesions, trauma, infection, or malignant infiltration. The exact pathogenesis is unknown, although it is noted to follow viral infection in approximately 30% of patients and commonly is termed postinfectious myelitis.[34,35] Other postulated etiologic categories include infectious, autoimmune, and idiopathic.[35-37] No apparent cause of acute transverse myelitis is identified in 30% of the patients.[35] Progression of symptoms usually is rapid, with 66% of the cases reaching maximal deficit by 24 hours.[38] Symptoms may progress, however, during days to weeks. The thoracic cord region is affected in 60 to 70% of cases[38]; the cervical spinal cord is rarely affected.[39]

Clinical Features. In addition to motor, sensory, and urinary disturbances, patients with acute transverse myelitis may complain of back pain and may have low-grade fever, raising concern for spinal epidural abscess. As with MS, the examination may reveal weakness progressing to paresis, hypertonia, hyperreflexia, clonus, and Babinski's response. Spinal cord involvement also can result in dysautonomias.

Diagnostic Strategies. Evaluation for acute transverse myelitis is done primarily with emergent MRI to exclude compressive lesions. Results of CSF studies are normal in 40% of the cases, with only mildly elevated protein level or pleocytosis in the remaining 60%.[40] The most essential aspect of the evaluation is to eliminate a potentially treatable cause, such as spinal epidural abscess, neoplasm, or hematoma.

Differential Considerations. Considerations in the differential diagnosis for transverse myelitis include MS, spinal epidural abscess, spinal neoplasm, and hematoma.

Management. Treatment with steroids is of unknown benefit. Anecdotal reports of improvement after steroid administration exist,[38,41] but some studies have found no benefit to their use.[37] Neurologic consultation is suggested, and hospitalization usually is required.

The clinical course of acute transverse myelitis varies widely, ranging from complete recovery to death from progressive neurologic compromise.[37] Maximal improvement usually is obtained within 3 to 6 months.[42,43] At 5-year follow-up evaluation of one series of patients with this disease, 30% had a good recovery, 25% had a fair recovery, 30% had a poor outcome, and 15% had died as a result of complications of the disease.[43]

Spinal Subarachnoid Hemorrhage

Principles of Disease. Intraspinal hemorrhage is rare and may occur in the same anatomic locations as intracranial hemorrhages; epidural, subdural, subarachnoid, and intramedullary hemorrhages are all possible.[5] Spinal subarachnoid hemorrhage usually is caused by an arteriovenous malformation.[44] Hemorrhage from tumors or cavernous angiomas and spontaneous hemorrhage secondary to anticoagulation therapy also have been reported.[45,46] Bleeding may occur exclusively in the subarachnoid space or within the substance of the spinal cord itself.

www.ketabpezeshki.com 66485457-66963820

Clinical Features. Patients present with excruciating back pain, of paroxysmal onset, at the level of the hemorrhage. This pain also may be in a radicular distribution or extend into the flank. Patients may complain of headache and exhibit cervical rigidity if the blood migrates into the intracranial subarachnoid space, simulating an intracranial subarachnoid hemorrhage. Variable neurologic deficits depend on the magnitude and anatomic location of the hemorrhage. These deficits typically include extremity numbness, weakness, and sphincter dysfunction.[45,47] Nuchal rigidity or signs of meningeal irritation may also be present.

Diagnostic Strategies. The diagnostic study of choice is MRI. Lumbar puncture also can confirm the presence of blood in the CSF.

Differential Considerations. Considerations in the differential diagnosis include epidural abscess, tumor, transverse myelitis, ischemia from aortic dissection, and anterior spinal artery thrombosis.

Management. Treatment depends on the etiology of the hemorrhage. Neurosurgical referral is obtained for further evaluation and for clot evacuation if compression is present. Angiography may be recommended if arteriovenous malformation is suspected.

Syringomyelia

Principles of Disease. Syringomyelia is the presence of a cavitary lesion within the substance of the spinal cord. A syrinx usually is a chronic progressive lesion, and its location within the cord determines the constellation of neurologic findings on examination.

Clinical Features. Headache and neck pain are the most common complaints, followed by sensory disturbance, gait disorder, and lower cranial nerve dysfunction.[48] The classic pattern of sensory deficit involves a loss of pain and temperature sensation in the upper extremities with preservation of proprioception and light touch. This phenomenon is described as a "dissociative anesthesia" because of the discrepant loss of sensory modalities. The sensory deficit often is described as being in a "capelike" distribution over the shoulders and arms. The anatomic basis for the neurologic features of a syrinx is the location near the central canal. Crossing fibers of the lateral spinothalamic tract carrying pain and temperature fibers may be impaired. Crude touch, position, and vibratory sensation typically are unaffected. Sensory fibers from the lower limbs are similarly spared.

The symptoms of syringomyelia develop and progress in accordance with the intracavitary pressure and location of the syrinx. The most common features on physical examination are lower limb hyperreflexia, weakness and wasting in the hands and arms, dissociated sensory loss, and gait disorder. Symptoms may be exacerbated by a sneeze, cough, or Valsalva maneuver.[49] Ninety percent of patients with syringomyelia have Arnold-Chiari I malformation (projection of cerebellar tonsils and medulla into the spinal canal).[50] Syringomyelia also may result from spinal cord trauma (often months to years later) or compressive tumors, or it may follow meningitis.[51]

Diagnostic Strategies. Syringomyelia is best seen on MRI. No other study currently in widespread use is equal to MRI in diagnostic ability.

Differential Considerations. Considerations in the differential diagnosis for syrinx include intrinsic spinal tumor and demyelination.

Management. When the diagnosis of syringomyelia is considered, emergent imaging in the ED is not necessary if follow-up evaluation can be arranged because this condition usually is a slowly progressive process. In patients for whom MRI studies are obtained and the diagnosis is made, referral to a neurosurgeon is indicated because symptoms progress in approximately two thirds of patients.[52]

Idiopathic Spastic Paraparesis

Idiopathic spastic paraparesis is a progressive disorder characterized by progressive weakness and signs of spasticity of the lower extremities. This condition sometimes also is referred to as primary lateral sclerosis, which describes the demyelination pattern in the lateral column of the spinal cord. This disorder typically occurs in older men. A heritable form may sometimes be discovered. It is a diagnosis of exclusion.[53-55]

Human Immunodeficiency Virus Myelopathy

HIV myelopathy typically occurs in patients with advanced HIV disease. Weakness, gait disturbance, sphincter dysfunction, sensory abnormalities, and signs of spasticity are features of this progressive process. This is a diagnosis of exclusion because disorders such as toxoplasmosis, lymphoma, varicella-zoster, and cytomegalovirus infection may produce a similar clinical picture in immunocompromised patients. On pathologic examination, vacuolization of myelin sheaths in the cord may be found. Treatment is directed at the retroviral infection, although there is no proven treatment.[56,57]

Spinal Cord Infarction

Spinal cord infarction is another diagnosis of exclusion. Aortic dissection, surgery, and global ischemia are the more common causes, although this disorder may occur as a complication of systemic lupus erythematosus or may be cryptogenic. An anterior spinal cord syndrome is the most common clinical picture. Some recovery is possible, although it generally is less complete than in cerebral stroke. The site of clinical dysfunction may be distant from the site of vascular occlusion.[58]

Extrinsic Cord Lesions

Spinal Epidural Hematoma

Principles of Disease. Spinal epidural hematoma is a relatively rare condition resulting from a variety of etiologic disorders. Its incidence is 0.1 per 100,000 population.[59,60] The etiology may be traumatic after lumbar puncture, epidural anesthesia, or spinal surgery.[1,5,61] Spinal epidural hematoma is more likely to occur in anticoagulated or thrombocytopenic patients or in patients with liver disease or alcoholism.[62] Spontaneous bleeding is rare but may arise from spinal arteriovenous malformation or vertebral hemangioma. Approximately one fourth to one third of all cases are associated with anticoagulation therapy, including low-molecular-weight heparin.[63,64]

Clinical Features. The patient usually presents with sudden, severe, constant back pain with a radicular component. It may be noted to follow a straining episode. The pain may be worsened by percussion over the spine and maneuvers that increase intraspinal pressure, such as coughing, sneezing, or straining.[65] The pain often causes the patient to seek care before the development of neurologic signs, possibly leading to delays in diagnosis.[5] Neurologic deficits follow and may progress during hours to days.[60] Anticoagulant use or an intrinsic coagulation abnormality may be present.

The patient usually is in significant distress from the pain. Motor and sensory findings depend entirely on the level and size of the hematoma but can include weakness, paresis, loss of bowel or bladder function, and virtually any sensory deficit.

Diagnostic Strategies. MRI, as with virtually all suspected intrinsic spinal disorders, is the diagnostic study of choice.[65]

Differential Considerations. Considerations in the differential diagnosis include abscess, epidural neoplasm, acute disk herniation, and spinal subarachnoid hemorrhage.

www.ketabpezeshki.com 66485457-66963820

Management. Recovery without surgery is rare, and surgical consultation for emergent decompressive laminectomy should be considered. The overall mortality rate is approximately 8%.[60,65] Functional recovery is related primarily to the length of time the symptoms are present. Recovery after 72 hours of symptoms is rare but has been reported even without surgery.[66,67]

Spinal Epidural Abscess

Principles of Disease. Spinal epidural abscess is an infectious process usually confined to the adipose tissue of the dorsal epidural space, where there is a rich venous plexus. It is an uncommon disease, with an overall frequency of 0.2 to 1.2 per 10,000 hospital admissions.[68,69] Major risk factors include diabetes, injection drug abuse, chronic renal failure, alcoholism, and immunosuppression, although the disease can be seen in patients who have none of these conditions.[69-71] Whereas the disease may be manifested in subacute and chronic forms, the acute presentation is seen most frequently in the ED. Thoracic and lumbar sites of infection predominate, with cervical epidural abscess being much less common.[72,73] Infection typically extends over four or five spinal vertebral segments.[74] The dura mater limits the spread of an epidural infection, making subdural or intraspinal spread uncommon. Hematogenous spread of infection to the epidural space is the most common source (seen in 26-50% of cases),[5,68,74] either to the epidural space or to the vertebra with extension to the epidural space. Skin and soft tissue infections are the most frequently reported identified source (in 15%)[70,74]; *Staphylococcus aureus* is the most prevalent organism, being cultured in more than 50% of cases.[68,75] Other frequently identified pathogens include aerobic and anaerobic streptococci, *Escherichia coli,* and *Pseudomonas aeruginosa*. Multiple organisms are identified in approximately 10% of cases; no organism is identified in 40%.[65,72]

Clinical Features. The classic clinical presentation of spinal epidural abscess begins with a backache that progresses to localized back pain often associated with tenderness to percussion. The duration of symptoms is typically a few days but may extend for weeks. Fever, sweats, and rigors are common, being reported in 30 to 75% of patients.[68,75] The classic triad of back pain, fever, and progressive neurologic deficits is present in only a few patients, however, and delayed clinical diagnosis is common.[68] Radicular symptoms may not be present initially but usually develop as the disease progresses.

Without treatment, myelopathic signs will develop, usually beginning with bowel and bladder disturbance. Weakness ensues, followed by paraplegia or quadriplegia. Approximately 10% of patients with spinal epidural abscess present with altered mental status due to encephalopathy.[68,74]

Diagnostic Strategies. MRI is the imaging modality of choice and needs to be performed emergently if the diagnosis is entertained. Other diagnostic testing is nonspecific for spinal epidural abscess, but a complete blood count may support the diagnosis because leukocytosis is commonly present, with a typical white blood cell count of 13,000 to 16,000/μL.[74] The erythrocyte sedimentation rate, although not specific for epidural abscess, is virtually always elevated with this condition.[68,69,74] Plain films usually are normal in appearance unless evidence of osteomyelitis of an adjacent vertebral body is seen. Lumbar puncture is relatively contraindicated with known epidural abscess but is often performed as part of the evaluation for meningitis. CSF findings are consistent with a parameningeal infection, showing elevation of protein and some increase in inflammatory cells.

Differential Considerations. Any compressive spinal lesion, including tumor or hematoma, can mimic spinal epidural abscess.

Management. Urgent surgical consultation for decompression usually is required. Antibiotics effective against the most common pathogens (particularly *S. aureus*) should be started empirically. One such regimen that covers gram-positive and gram-negative organisms consists of a third-generation cephalosporin plus vancomycin, both given intravenously, plus rifampin given orally.

Outcome is usually related to the speed of diagnosis before the development of myelopathic signs. The disease is fatal in 18 to 23% of cases, and patients with neurologic deficit rarely improve if surgical intervention is delayed more than 12 to 36 hours after onset of paralysis.[68,74] Patients operated on before development of neurologic symptoms have an almost universally good outcome.[69,70]

Diskitis

Principles of Disease. Diskitis is an uncommon primary infection of the nucleus pulposus, with secondary involvement of the cartilaginous endplate and vertebral body. It may occur after surgical procedures or spontaneously, the latter being more common in pediatric patients.[76,77] An increased incidence of diskitis has been noted in immunocompromised patients and in patients with systemic infections. Both a chronic disease and a more common acute course have been described.[76]

Clinical Features. Patients present with moderate to severe pain, localized to the level of involvement and exacerbated by almost any movement of the spine. Radicular symptoms are present in 50 to 90% of cases.[76,77] The lumbar spine is the most common site of disease. Elevated temperature is noted in more than 90% of patients.[76] Patients experience pain with range of motion. Neurologic deficits are the exception with diskitis.

Diagnostic Strategies. Plain radiographs usually are not helpful for early diagnosis, but destruction of the disk space is highly suggestive if present. The radiographic findings become abnormal after 2 to 4 weeks of disease. In addition to disk space narrowing, plain films may show irregular destruction of the vertebral body endplates. Often there is a latent period (2 to 8 weeks) between the onset of back pain and the development of other clinical symptoms or abnormalities on the physical examination. MRI is the radiographic study of choice because it can not only diagnose diskitis but also rule out paravertebral or epidural abscess. Laboratory studies often show an elevated erythrocyte sedimentation rate, but the white blood cell count usually is normal.[76,77] *S. aureus* is the most common pathogen, but gram-negative, fungal, and tuberculous infections all have been recognized.

Differential Considerations. Considerations in the differential diagnosis include vertebral osteomyelitis, spinal epidural abscess, neoplasm, and hematoma.

Management. With timely diagnosis and treatment, outcome generally is good, and medical treatment with intravenous antibiotics usually is curative. Surgery often is not necessary.[76,77]

Neoplasm

Principles of Disease. Spinal cord tumors are classified according to their relationship to the dura and spinal cord (extradural, intradural extramedullary, and intradural intramedullary). Spinal cord tumors produce neurologic symptoms by compression, invasion, or destruction of myelinated tracts. The resulting neurologic symptoms are directly related to the growth rate and the location of the tumor. Spinal cord tumors account for 4 to 10% of central nervous system tumors but for only 1% of all cancers. Primary tumors occur with an incidence of 1 per 1 million population.[78] Most tumors affecting the spinal cord are metastatic. Approximately 10% of patients with known cancer are diagnosed with a spinal metastasis at some point in the course of their disease, and 5 to 10% of patients ultimately diagnosed with cancer first present with a spinal metastasis.[2] Lung cancer, breast cancer, and lymphoma represent more than 50% of the primary malignant neoplasms that subsequently develop spinal metastasis, spreading by both the hematogenous route and direct extension. Most

www.ketabpezeshki.com 66485457-66963820

metastases occur in the thoracic spine, and nearly 20% of patients with tumor spread to the spine will be found to have disease at multiple levels.[2,79,80]

Clinical Features. In 95% of patients with spinal neoplasm, the initial complaint is pain, either in the back at the level of the tumor or in a radicular distribution. Pain often is characterized as dull, constant, and aching and commonly is said to worsen with recumbency (in contrast with the pain of herniated disk).[5] Nighttime pain that is severe is characteristic of spinal neoplasm.[81] Any action that increases intraspinal pressure (Valsalva maneuver, sneeze, cough) may be associated with increased pain. Neurologic deficits vary by the location of the lesion. Besides a thorough neurologic examination, a search for possible primary sites should be done on the physical examination.

Diagnostic Strategies. Plain radiographs are usually the initial diagnostic test, and 70 to 85% of patients with spinal column involvement show some abnormality on these films.[81] Patients with neurologic abnormalities and suspicious findings on plain films are candidates for emergent MRI or CT myelography. In patients with a known history of neoplasm and new back pain, some authorities recommend foregoing plain films and proceeding directly to MRI because plain films can be misleading or nondiagnostic.[82]

Differential Considerations. Considerations in the differential diagnosis include any of the compressive lesions (hematoma, infection). Tumor can also mimic intrinsic spinal cord lesions, such as transverse myelopathy and cord infarction.

Management. Acute compressive myelopathy from neoplasm constitutes an oncologic emergency. Immediate treatment is required to preserve function and to prevent deterioration. With onset of paraplegia and incontinence, less than 5% of patients regain ambulatory status.[1,83] Of patients who are ambulatory at the time of diagnosis, 60% remain ambulatory.[5] High-dose steroids, radiotherapy, and surgery all may be necessary acute interventions, and consultation with neurosurgeons, neurologists, oncologists, and therapeutic radiologists may be required.

KEY CONCEPTS

- Spinal cord disorders may be manifested in subtle fashion and with nonspecific clinical signs and symptoms. In the absence of neurologic abnormalities or complaints, diagnosis of these disorders can be extremely difficult.
- Patients with rapid onset and progression of spinal cord symptoms should receive specialized imaging and consultation in the ED.
- MRI frequently is required for a definitive diagnosis of spinal cord syndromes.
- With compressive lesions of the spinal cord, duration of neurologic dysfunction is directly related to ultimate neurologic outcome. The diagnosis should be made expeditiously and definitive therapy begun as soon as possible.

Chapter 107

Peripheral Nerve Disorders

E. Bradshaw Bunney and E. John Gallagher

PERSPECTIVE

Background

The nervous system is traditionally divided into central nervous system (CNS) and peripheral nervous system (PNS) components. The PNS can be further subdivided into 12 cranial and 31 spinal nerves. Disorders of the cranial nerves are discussed in Chapter 105. Because diseases of the neuromuscular junction and the myopathies are located distal to the neuron itself, they are also considered separately in Chapter 108. Radiculopathies, which are disorders of the roots of the PNS, are so commonly associated with musculoskeletal neck and back pain that they are mentioned only briefly here and are discussed in detail in Chapter 54.

The simplest approach to diseases of the PNS parallels the CNS model of separating focal from nonfocal disease. In the PNS, the first broad category is the focal group, which can be divided into those with evidence of single versus multiple lesions of peripheral nerves, known respectively as *simple mononeuropathies* and *multiple mononeuropathies* (or *mononeuropathy multiplex*). The second broad category, which constitutes the nonfocal group of peripheral neuropathies, contains the polyneuropathies. These tend to produce bilaterally symmetrical symptoms and signs, reflecting the widespread nature of the underlying pathologic process.

The evaluation of PNS disease involves a goal-directed history and physical examination targeted at answering the following three questions, each of which corresponds to a stratum of the algorithm presented in Figure 107-1:

1. Are the sensorimotor signs and symptoms symmetrical or asymmetrical?
2. Are the sensorimotor signs and symptoms distal or both proximal and distal?
3. Is the modality involved exclusively motor, sensory, or mixed sensorimotor?

By systematically combining responses to these questions, one can identify seven discrete categories of peripheral neuropathy, each of which contains a finite set of possible diagnoses. Because pure motor or sensory findings tend to occur mainly in an asymmetrical, distal distribution, this is the only category in Figure 107-1 subdivided into pure motor and pure sensory abnormalities.

Epidemiology

Although Guillain-Barré syndrome (GBS) is the most commonly encountered emergent peripheral neuropathy in developed countries, its annual incidence is just 1 or 2 cases per 100,000 population.[1] In contrast to the acute peripheral neuropathies, several of which are associated with short-term mortality, most peripheral neuropathies seen in the emergency department (ED) are subacute or chronic and are associated not with mortality but with long-term morbidity.

Current estimates suggest that about 1.5% of the U.S. population suffers from peripheral neuropathy.[2] Diabetes mellitus is a leading contributor. More than 7% of the population has diabetes mellitus, with a prevalence rate of 20% in individuals older than 60 years. Roughly 50% of these individuals develop peripheral neuropathy.[3]

PRINCIPLES OF DISEASE

Anatomy

The spinal component of the PNS is shown schematically in Figure 107-2. The anterior and posterior nerve roots exit the spinal cord at each segmental level. Just distal to the dorsal root ganglion they converge to form a mixed (motor and sensory) spinal nerve, of which there are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The spinal nerves immediately bifurcate into anterior (ventral) and posterior (dorsal) rami. The posterior ramus travels to the back. The anterior ramus innervates the anterolateral portion of the body and supplies all peripheral nerves for the upper and lower extremities through the brachial and lumbosacral plexus, respectively. Interweaving of fibers occurs within a plexus, producing a mixed sensorimotor innervation of peripheral nerves exiting the plexus.

In addition to the motor and sensory modalities of the PNS, the autonomic nervous system has a peripheral component. Anatomically and functionally, the autonomic nervous system is divided into two parts: a sympathetic (thoracolumbar) component and a parasympathetic (craniosacral) component. Autonomic dysfunction may cause systemic abnormalities, such as orthostasis, or local problems, such as atrophic, dry skin.

Pathophysiology

The PNS has only three basic responses to a wide array of pathologic stimuli. As shown in Figure 107-2, these are (1) the myelinopathies, in which the primary site of involvement is limited to the myelin sheath surrounding the axon; (2) the axonopathies, in which the primary site of involvement is the axon, with or without secondary demyelination; and (3) the neuronopathies, in which the cell body of the neuron itself is the primary site of involvement, ultimately affecting the entire peripheral nerve. Although overlap occurs, each of these prototypes has a distinctive clinical presentation, electrophysiologic profile, and microscopic appearance.

Electrophysiologic testing, that is, nerve conduction studies (NCSs) and needle electromyography (EMG), detects underlying pathologic abnormalities. Because neither test is readily available in the acute care setting, they are discussed only briefly here. Information gathered from NCSs and EMG can be used to obtain objective information on the anatomic distribution of involvement (symmetrical vs. asymmetrical and distal vs. proximal and distal) and the modalities involved (sensory, motor, or mixed). NCSs and EMG can also identify the level of the neuraxis affected by the disease process (i.e., root, plexus, or nerve); if the nerve is affected, electrophysiologic testing can help determine whether the lesion is mononeuropathic (either an isolated mononeuropathy or mononeuropathy multiplex) or polyneuropathic. Finally, EMG and NCSs can distinguish axonal from myelin disease, further narrowing the differential diagnosis. Prognosis is determined by the nature of pathologic involvement of the PNS. Primary demyelination spares the axon and thus carries the best prognosis. The prognosis is worse in axonopathies because reestablishment of nerve function is dependent on the much slower process of axonal regeneration. Neuronopathies, which begin with primary destruction of the nerve cell body, produce pure motor or pure sensory syndromes. Eventually the entire nerve is affected, resulting in the worst prognosis of the three.

are localized to the extremities, should include a peripheral neuropathy. Within this group, patients with focal weakness are most concerning because they are at greatest risk for respiratory compromise. Box 107-1 lists the causes of acute, emergent weakness that may affect respiration. Although several of the disorders listed are myopathies (see Chapter 108) rather than peripheral neuropathies, they are lumped together because it is important to identify patients at risk for respiratory failure early in the course of evaluation.

As soon as the emergent causes of weakness have been excluded, which is possible in the majority of patients, the individuals with focal weakness should be assessed next to exclude CNS disease (e.g., stroke; see Chapter 101). One can then proceed through the systematic approach to peripheral neuropathy outlined in Figure 107-1. Another way to look at the algorithm displayed in Figure 107-1 is shown in Table 107-1, with the distinguishing features of each of the seven peripheral neuropathic patterns described by distribution and modality and represented by a disease prototype.

Type 1: Demyelinating Polyneuropathies

The pattern of symmetrical weakness, usually worse distally, accompanied by variable sensory findings is characteristic of acute GBS. This pattern is discussed first because it is the most common cause of weakness associated with acute respiratory failure.

Guillain-Barré Syndrome

GBS is a heterogeneous and unpredictable disorder, with marked variation in latency between antecedent infection and symptom onset. The clinical signs, cadence of disease progression, degree of respiratory compromise, laboratory findings, and time required for convalescence are also highly variable. The most common form of GBS is an acute inflammatory demyelinating polyneuropathy, representing 90% of the cases seen in the United States.[1] Less common variants are acute motor axonal neuropathy, acute motor and sensory axonal neuropathy, and the Miller Fisher syndrome. Acute motor axonal neuropathy, which accounts for most of the remaining cases seen in the United States, afflicts those of Asian descent. Miller Fisher syndrome is a rare form of GBS characterized by the triad of ophthalmoplegia, ataxia, and areflexia (Box 107-2).[1,4]

The majority of patients seek treatment days to weeks after resolution of an upper respiratory or gastrointestinal illness, presenting with progressive, symmetrical distal (and usually to a lesser extent proximal) weakness. Signs and symptoms are usually worse in the lower extremities and are associated with diminution or loss of deep tendon reflexes (DTRs), variable sensory findings, and sparing of the anal sphincter. Up to 32% will have all four extremities affected at the time of presentation, but only 10% will have weakness that begins in the upper extremities.[1] The ocular muscles are usually spared. Urinary retention secondary to autonomic dysfunction may occur, contributing to a clinical picture easily mistaken for a spinal cord lesion or conus medullaris syndrome.

The most commonly infectious organisms associated with GBS are *Campylobacter jejuni* (in patients with a history of diarrhea), cytomegalovirus, Epstein-Barr virus, and *Mycoplasma pneumoniae.* Acute inflammatory demyelinating polyneuropathy is caused in part by macrophage invasion of the myelin sheath. The macrophage is believed to detect antigens in the myelin that are nearly identical to the antigens present on certain infectious organisms.[1,5,6]

In practice, patients with symmetrical weakness of relatively acute onset, decreased or absent DTRs, and variable degrees of sensory loss are managed as if they have GBS or one of its variants.

These patients have a greater risk for respiratory compromise. Conversely, patients with predominantly sensory signs and symptoms are less likely to develop acute respiratory distress and have a more favorable prognosis.[7]

About half of patients with GBS have autonomic dysfunction, experience a peak of disease severity within a week of onset, have some form of cranial nerve involvement (usually VII), and suffer long-term sequelae of their illness. Nearly one third require ventilatory support. Both the mortality and the recurrence rate are about 3%.[8]

In addition to electrophysiologic testing, there are three ancillary tests that may be helpful in the diagnosis of GBS. Cerebrospinal fluid (CSF) analysis is useful when it demonstrates the characteristic picture of markedly elevated protein with only a mild pleocytosis. In the clinical setting of suspected GBS, this finding is highly specific. Early in the disease, however, patients may have normal CSF values. Consequently, a normal CSF value cannot be used to exclude GBS because of the limited sensitivity of this test. Specific protein levels in the CSF (neurofilament NfH) have been shown to correlate with outcomes.[9] The GBS disability score, which combines age, presence or absence of diarrhea, and a score of the patient's ability to ambulate independently at 2 weeks, has been shown to be predictive of prognosis at 6 months, particularly related to independent activity.[10] Tongue weakness has been found to be associated with the development of respiratory compromise and the need for mechanical ventilation in patients with GBS.[11]

Management. Individuals with suspected GBS should have their respiratory function tested. A decrease in forced vital capacity (FVC) has been shown to correlate with the need for intubation in patients with GBS. An FVC of less than 20 mL/kg is associated with pending respiratory failure and the need for intubation, whereas patients with an FVC of more than 40 mL/kg do not usually require intubation.[12,13] Likewise, patients with a negative inspiratory force of less than 30 cm H_2O are more likely to require mechanical ventilation.[13] Other tests, such as the forced expiratory volume in 1 second and peak flow rate, can also be used to assess respiratory function. Patients unable to perform these tests and those with less than 100% of predicted values should have an arterial blood gas sample obtained. Evidence of alveolar hypoventilation (elevated carbon dioxide [P_{CO_2}]) in a patient with an unsecured airway requires a level of intensive monitoring that is impractical in many EDs. Therefore, patients with weakness, carbon dioxide retention, or other evidence of early ventilatory failure should be considered for early, prophylactic intubation.[14]

Among patients with possible GBS who have normal pulmonary function, extensor neck strength can be monitored to predict impending ventilatory failure. Patients with probable GBS should receive neurologic consultation and admission for treatment with either plasma exchange or intravenous immune globulin (IVIG). There is sound evidence that both of these treatments are superior to placebo and that combination or sequential therapy confers no therapeutic advantage over either intervention alone. Plasma exchange is cumbersome and not available at many hospitals. IVIG is more readily available and is usually administered in a dose of 400 mg/kg/day for 5 days. However, IVIG is expensive, costing roughly $50 to $80 per gram.[15,16] Although IVIG is not formally approved by the Food and Drug Administration for this purpose, its use is supported in national treatment guidelines.[17] Corticosteroids are no longer recommended for treatment of GBS.[18] Oral steroids have been shown to delay recovery. Intravenous steroids alone have been shown to impart no benefit, and although the combination of intravenous steroids and IVIG has hastened recovery, there was no effect on long-term outcome.[18-21] The marked elevation in blood pressure seen in some patients with GBS should not be treated because it is typically transient and may be followed by precipitous and unpredictable hypotension.

Compared with adults, children who have GBS have neuropathic pain more often (80%) and require mechanical ventilation less often (13%).[16, 22]

Type 2: Distal Symmetrical Polyneuropathies

Most polyneuropathies are characterized by a pattern of distal, symmetrical sensorimotor findings, worse in the lower than in the upper extremities, with a stocking-glove distribution of sensory abnormalities that gradually diminishes as one moves proximally. Motor weakness and loss of DTRs, which lag behind the sensory features, follow a similar pattern of progression from distal to proximal. The diffuse, distal, symmetrical nature of this pattern is most consistent with a toxic-metabolic disease process, as yet unidentified, that causes a length-dependent axonopathy. Distal symmetrical polyneuropathy (DSPN) is the most common type of peripheral neuropathy. Only the most common causes of DSPN are discussed, with a more complete listing of causes shown in Box 107-3.

Diabetic Distal Symmetrical Polyneuropathy

The preponderance of cases of DSPN occur in diabetics, also termed diabetic polyneuropathy. Initial symptoms usually consist of "positive" sensory complaints (e.g., dysesthesias such as tingling and burning) beginning on the plantar surfaces of both feet. At the early stages of a typical DSPN, there may be some asymmetry. At this juncture, it may be impossible to distinguish a focal neuropathic process such as a mononeuropathy from a polyneuropathy, although in this location, prior probability strongly favors a polyneuropathy. As the process advances, the plantar surfaces of both feet become dysesthetic before the dorsum of either foot is involved. Weakness of dorsiflexion of the big toe is usually the first motor sign, followed by weakness of foot dorsiflexion, footdrop, loss of the Achilles reflex, and later a "steppage gait," in which footdrop causes the toes to point downward and scrape the ground while walking, requiring the patient to lift the leg higher than normal when walking.

Sensory loss continues to move proximally, and before it reaches the knees, the fingertips are usually involved. DTRs are progressively lost, as is proprioception. If loss of proprioception becomes severe, patients may develop sensory ataxia. As the neuropathy continues to progress, sensory abnormalities ultimately involve all modalities and extend to a diamond-shaped periumbilical area. Far-advanced disease may affect sensation over the skull vertex and facial midline structures. Atrophy and areflexia occur as weakness worsens. Severely impaired patients may be unable to ambulate or to grasp objects. These symptoms have a significant impact on the patient's quality of life, affecting not only physical

functioning but also sleep and emotional and social functioning. Many of these patients display signs of depression or anxiety.[23] Polyneuropathies can be difficult to diagnose and are best approached by the performance of electrodiagnostic studies for patients with a constellation of symptoms and signs suggesting a particular neuropathy.[24]

Management. As with virtually all peripheral neuropathies, referral is indicated for management of diabetic DSPNs. If discomfort is severe, the etiology of the neuropathy seems likely to be diabetic, and if referral is delayed, it may be necessary to provide the patient with some symptomatic relief. Because treatment of neuropathic pain has traditionally been linked to etiology rather than to an underlying mechanism, the choice of pharmacologic agents is empirical, with substantial practice variation in the United States and worldwide. The costs for patients and health plans are considerable; patients will typically spend more than $1000 per year for pain relief from diabetic DSPN.[9] Nonsteroidal anti-inflammatory drugs should not be considered first-line treatment because they have little proven efficacy and a high potential for renal impairment.[3] On the basis of placebo-controlled randomized clinical trials, tricyclic antidepressants and anticonvulsants appear to have the best NNTs (number of patients needed to treat to provide at least 50% relief of symptoms in one patient). These are generally in the range of 3 to 5, with confidence intervals whose upper limits reach 10 in some instances.[25] Imipramine or amitriptyline may be started at a dose of 25 mg at bedtime (10 mg in elders) and titrated slowly up to a dose of 300 mg. Carbamazepine at a dose of 200 to 400 mg every 8 hours and gabapentin at a dose of 900 to 3600 mg/day are also effective treatments.[2,26] Tramadol in two studies has shown an NNT below 5.[24] Although tramadol is a mixed opioid, development of dependence in long-term use appears to be uncommon. Tramadol combined with acetaminophen has been found to be as effective as gabapentin in the treatment of painful diabetic neuropathy.[27] In a recently published guideline, the following medications were recommended for the treatment of neuropathic pain: gabapentin, opioids, tramadol, and tricyclic antidepressants.[3] Pregabalin 150 to 600 mg/day, a more recent treatment option, has a mechanism of action similar to that of gabapentin. Duloxetine, a selective serotonin and norepinephrine reuptake inhibitor, has been found effective at a dose of 60 mg/day.[3] Recently, tapentadol ER 100 to 250 mg twice daily was found to provide substantial pain relief in patients with diabetic neuropathy.[28] Topical capsaicin provides relief in some patients, but the burning associated with its application has limited its use. Improving glycemic control can prevent, diminish, or reverse early diabetic DSPNs, and even in diabetic patients with severe peripheral neuropathy, tight glycemic control can improve functionality and pain control.[29]

Alcoholic Distal Symmetrical Polyneuropathy

Although the association between alcoholism and peripheral neuropathy has been well established for centuries, demonstration of a direct neurotoxic effect of alcohol remains elusive. The preponderance of evidence from both observational studies in humans and experimental data from animal models suggests that the association between alcohol and peripheral neuropathy may be confounded by nutritional status (i.e., deficiency states might be the true underlying cause of alcoholic peripheral neuropathy).

The clinical and pathologic picture of alcoholic neuropathy is similar to that of the DSPN of diabetes. However, in alcoholism, severe myopathy and cerebellar degeneration often complicate the clinical picture.[30] Autonomic skin changes with atrophy and hair loss accompany the sensorimotor abnormalities. Often, other systemic effects of alcoholism are so severe that the patient may not notice the neuropathic symptoms. All patients with suspected alcoholic DSPN should receive dietary supplements and referral for outpatient management.

Human Immunodeficiency Virus Neuropathies

With the widespread use of highly active and effective antiretroviral treatment, peripheral neuropathies have become the most common neurologic complication of human immunodeficiency virus (HIV) infection. The typical HIV neuropathy is a DSPN that appears to be triggered by a combination of dideoxynucleoside therapy and poorly characterized immune-mediated mechanisms associated with HIV infection.[31,32] These patients require referral for specialized care. In addition to standard therapies for DSPN,

lamotrigine has been shown to be moderately effective in the treatment of HIV-associated painful neuropathies.[33]

Toxic and Metabolic Neuropathies

Many toxic agents and metabolic derangements produce a typical DSPN. Box 107-3 lists some of the most common toxic and metabolic causes of peripheral neuropathy. On the basis of preliminary results from a case-control study, the statins have been added to this list.[34]

Type 3: Asymmetrical Proximal and Distal Peripheral Neuropathies (Radiculopathies and Plexopathies)

Radiculopathies are discussed in detail in Chapter 54. Plexopathies, which are discussed briefly in this chapter, are uncommon and often the result of trauma (Box 107-4). In general, a plexopathy, whether brachial or lumbosacral, is identified by a process of elimination (i.e., a pattern of sensorimotor and reflex abnormalities that fit neither a radicular nor an individual peripheral nerve distribution). Although this approach does not exclude a mononeuropathy multiplex on physical examination alone, a careful history should determine whether the patient is at risk for development of a mononeuropathy or plexopathy on the basis of underlying disease.

Most plexopathies are often the result of blunt trauma and are usually seen in young men after motor vehicle accidents. Most present for evaluation several months after injury because of the need to recover from concurrent injuries. Therapeutic intervention is often delayed to maximize the potential for spontaneous recovery. Several surgical repairs exist, including neurotization and nerve transfer.[35]

Radiation (actinic) plexopathy occurs after a variable period of latency that follows treatment, which may extend to 20 years or more. Almost all series include women who received radiation treatment for breast cancer. Among neoplastic causes, most originate from the lung or breast. Patients with probable neoplastic brachial plexopathy need imaging studies and may require immediate radiation therapy. Pain control is the focus of management.

Thoracic outlet syndrome remains a controversial disorder.[36] Although the pendulum has swung during the past 50 years from a postulated vascular cause to a neurogenic etiology, current evidence supporting the high prevalence of compression of the brachial plexus as a cause of thoracic outlet syndrome is in fact only slightly better than earlier evidence favoring a vascular etiology.[37,38] Nevertheless, the disorder is currently thought to be most commonly due to compression of the medial or lower portion of the brachial plexus by a cervical rib or fibrous band.[39] The syndrome is characterized by gradually progressive weakness and wasting of median and ulnar hand muscles with ulnar forearm and hand sensory signs and symptoms. Patients with this clinical picture should be referred for NCSs and EMG, which are diagnostic.[39] The treatment of true neurogenic thoracic outlet syndrome requires surgical removal of the rib or aberrant fibrous band to decompress the brachial plexus.[39]

Because of the complexity of plexopathies, there is no reason to expect that one can or should do more in the ED than localize the probable pathologic process to the brachial or lumbosacral plexus. Depending on severity and suspected etiology, one should either admit or refer the patient to a neurologist with experience in PNS disease.

Type 4: Isolated Mononeuropathies

The pattern of asymmetrical, sensorimotor, usually distal, peripheral neuropathy is characteristic of a mononeuropathy. Mononeuropathies are of two main types: isolated and multiple. The isolated mononeuropathies are discussed in this section; the multiple mononeuropathies, also termed mononeuropathy multiplex, are discussed in the next section as a type 5 peripheral neuropathy.

Isolated mononeuropathies are usually caused by trauma, either blunt or penetrating (Box 107-5). If the trauma is blunt, the injury may be secondary to compression from an internal or external source. Entrapment neuropathies are a subset of compression neuropathies occurring at anatomic locations where nerves traverse potentially constricting compartments or tunnels. Isolated mononeuropathies may be acute, intermittent, or chronic and continuous. Antecedent peripheral neuropathy may be a risk factor for development of compression neuropathy (so-called double-crush syndrome), particularly in diabetics.

Radial Mononeuropathy

The radial nerve arises from C5-T1 roots. After exiting the brachial plexus, it passes behind the proximal humerus in the spiral groove and takes a lateral (radial) course down the upper arm (Fig. 107-3). At about the level of the antecubital fossa, it bifurcates into the posterior interosseous (pure motor) and superficial radial (pure sensory) nerves.

The radial nerve controls extension of the fingers, thumb, wrist, and elbow (triceps). In contrast to the median and ulnar nerves, the radial nerve provides only *extrinsic* motor innervation to the hand (i.e., it does not supply motor fibers to any muscles that both originate and insert within the hand). In further contrast to the median and ulnar nerves, which supply most of the sensation to the hand, the radial nerve makes a contribution only to a cutaneous dorsal area overlying the first dorsal interosseus muscle,

sometimes extending part of the way up the dorsa of the thumb, index, and long fingers.

Radial mononeuropathy caused by involvement at the level of the axilla is uncommon. When it occurs, it is usually associated with other upper extremity mononeuropathies or a brachial plexopathy. Although improper use of crutches may cause this syndrome, it usually occurs after an extended period of unconsciousness during which the arm is positioned in such a way that prolonged, deep compression is applied to the axilla. Axillary radial mononeuropathy is distinguished from the more common humeral form by the finding of triceps involvement in addition to typical wrist and finger drop. Triceps involvement occurs because the innervation to the triceps is proximal to the point where the nerve is most vulnerable as it winds around the humeral shaft (see Fig. 107-3).

Most radial mononeuropathies are due to so-called Saturday night palsies. The euphemism is derived from the association of radial mononeuropathy with improper positioning of the arm

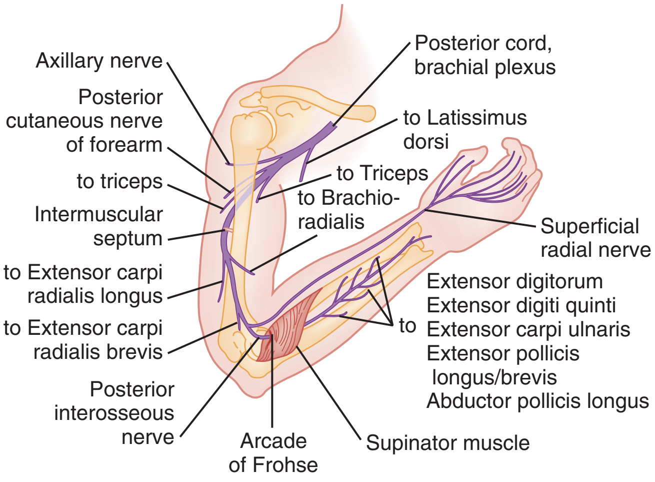

Figure 107-3. Radial nerve, major branches, right arm, lateral view. (From Stewart JD: Focal Peripheral Neuropathies, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

during deep, commonly inebriated sleep. Consequently, the radial nerve is trapped for a prolonged period between the humeral shaft and some firm surface, causing an external compression mononeuropathy. "Bridegroom's palsy" is another eponym for radial mononeuropathy, so named because the radial nerve may be compressed by the bride's head resting on the bridegroom's arm during sleep.

Because innervation of the wrist and finger extensors occurs distal to this area of the humeral shaft, findings are characterized by wrist and finger drop and mild numbness over the skin of the first dorsal interosseus muscle. Depending on the level, degree, and duration of compression, some fascicles of the nerve may remain functional, resulting in a partial radial mononeuropathy. Thus the superficial radial nerve may remain intact, resulting in no loss of sensation, or loss of wrist and finger extension may be incomplete.

Because the finger drop of radial mononeuropathy places the hand at a mechanical disadvantage, examination of ulnar function by testing of the interossei may produce false-positive findings of weakness. To adjust for this, the examiner should ask the patient to place the palm on a horizontal supporting surface, such as a stretcher. With the fingers extended and no longer "dropped" at the metacarpophalangeal joints, interosseous strength can now be fairly tested. Failure to perform this maneuver may cause misdiagnosis of a simple radial mononeuropathy as a brachial plexopathy in an effort to explain what appears to be radial and partial ulnar nerve involvement.

About 90% of radial nerve palsies occurring during sleep, coma, or anesthesia recover fully, usually within 6 to 8 weeks. Evidence of denervation on EMG studies predicts a slower rate of recovery. Tourniquet injuries to the radial nerve usually recover spontaneously within 2 to 4 months. If axonal degeneration is seen on electrophysiologic testing, recovery may take longer, although virtually all radial mononeuropathies caused by tourniquets eventually resolve. About 75% of radial nerve injuries associated with a closed humeral shaft fracture recover spontaneously. In contrast, surgical intervention is needed to free the nerve from entrapment associated with complex fractures.

While patients are waiting for spontaneous recovery to occur, the hand should be maintained in about 60 degrees of dorsiflexion. Although a simple dorsal plaster or fiberglass splint treats the wristdrop, atrophy and contractures can be minimized and function of the hand can be improved if wide rubber bands anchored to the splint at a point proximal to the wrist are attached to individual fingers to provide passive dorsiflexion.

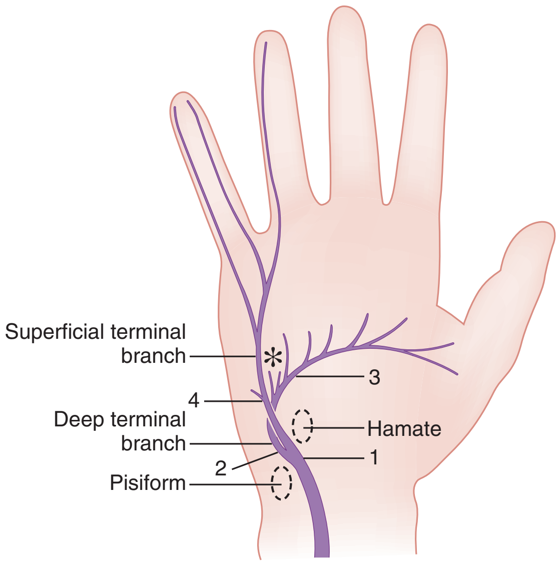

Figure 107-5. Distal ulnar nerve and branches, right hand, palmar view. Numbers indicate four main sites of distal ulnar mononeuropathy in the wrist and hand. *Denotes hypothenar branches. (From Stewart JD: Focal Peripheral Neuropathies, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

Ulnar Mononeuropathy

The ulnar nerve includes C7-T1 roots and passes through the brachial plexus to descend medially, without branching, to the ulnar (medial) condylar groove at the elbow. It then enters the cubital canal, where it gives off branches to the ulnar wrist flexor and the deep flexors of the fourth and fifth digits.

Just proximal to the wrist, two important sensory branches leave the main trunk to supply cutaneous sensation to part of the hand (Fig. 107-4). These are the palmar and dorsal cutaneous branches, which do *not* pass through Guyon's canal. The palmar branch supplies sensation to the hypothenar eminence and the dorsal branch innervates the ulnar side of the dorsum of the hand, extending out nearly to the tip of the fifth and ulnar half of the fourth digit.

At the wrist, the nerve enters Guyon's canal (Fig. 107-5) between the pisiform and hook of the hamate, then bifurcates into the superficial terminal sensory branch and the deep motor branch.

The superficial sensory nerve supplies ulnar sensation to the palmar side of the fifth and half of the fourth digit (see Fig. 107-5). The deep motor nerve supplies the hypothenar muscles, then crosses to the radial side of the palm to innervate the ulnar intrinsics (all interossei and the ulnar lumbricals of the fourth and fifth digits), terminating in the first dorsal interosseus. The interossei abduct and adduct the fingers and are all innervated by the ulnar nerve. The lumbrical muscles flex the metacarpophalangeal joints and are evenly divided between the ulnar (fourth and fifth) and median (second and third) digits. The ulnar nerve can be thought of as the complement to the median nerve in the hand because it supplies all of the muscles and all palmar sensation not innervated by the median nerve.

The ulnar nerve may be injured at two locations near the elbow: in the ulnar condylar groove and distally in the cubital canal. Because the condylar groove is shallow, the ulnar nerve runs superficially in this location and is vulnerable to injury, usually from external pressure or from a fracture or dislocation. The ulnar nerve has a propensity to develop a "tardy ulnar palsy," occurring years after a traumatic event. Many of these delayed ulnar mononeuropathies can be localized to the elbow on electrophysiologic testing.

Some ulnar mononeuropathies occur secondary to compression just proximal to entry into the cubital canal or are entrapped within the canal itself. Transient symptoms may occur during prolonged flexion or with repeated flexion and extension at the elbow.

Although it is difficult to distinguish a condylar from a cubital ulnar mononeuropathy, it is usually possible to localize the problem to the region of the elbow or the wrist. In addition to prior probability heavily favoring the elbow, the presence of sensory abnormalities in an ulnar distribution in the hand and fingers (i.e., usually including the fifth digit and "splitting" the fourth digit) strongly suggests that the lesion is at the level of the elbow rather than the wrist. The ulnar cutaneous innervation to the hand branches off from the main trunk proximal to the nerve entering Guyon's canal (see Figs. 107-4 and 107-5). Thus a lesion at the wrist should not produce sensory abnormalities, whereas one at the elbow would be expected to do so.

Compression of the ulnar nerve within Guyon's canal is rare. When it does occur, it affects all of the ulnar intrinsics (i.e., the two ulnar [fourth and fifth] lumbricals) and all the interossei. However, the ulnar extrinsics (i.e., the deep flexors of the fourth and fifth digits) are not affected, nor is the ulnar flexor of the wrist. The only sensory abnormalities are those in the distribution of the superficial terminal sensory branch, sparing other areas of ulnar innervation (see Fig. 107-5).

There are three ulnar mononeuropathies that occur distal to Guyon's canal in the hand. The two most common ones involve the deep terminal branch, either proximal or distal to the separation of the hypothenar branches (see Fig. 107-5). If the lesion is proximal, it produces weakness of all the ulnar innervated muscles

www.ketabpezeshki.com 66485457-66963820

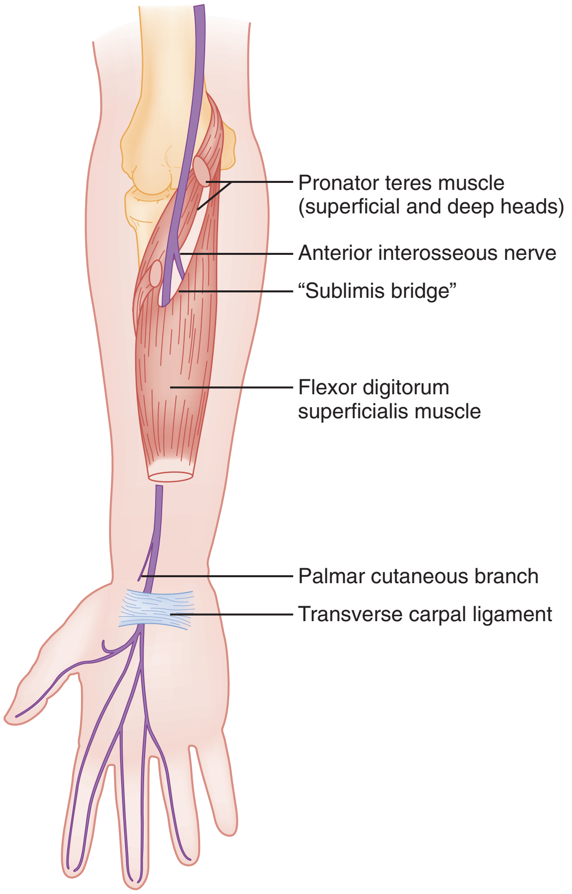

Figure 107-6. Median nerve, major branches, right arm, anterior view. (From Stewart JD: Focal Peripheral Neuropathies, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

of the hand without sensory loss. If it is distal, the hypothenar ulnar intrinsics are spared, but the picture is otherwise similar. Usually, this occurs secondary to a laceration or repeated compression in the hand from use of certain tools, a cane, or the handle of a crutch.

Involvement of the superficial terminal branch (see Fig. 107-5) produces a pure sensory loss of the palmar surface of the fifth digit and ulnar half of the fourth digit caused by direct compression of this branch just distal to Guyon's canal. The dorsal surface of these two digits should have normal sensation except for the distal tips. This configuration of findings is due to the intact innervation provided by the dorsal and palmar cutaneous branches that enter the hand without passing through Guyon's canal (see Fig. 107-4).

Most ulnar mononeuropathies will spontaneously resolve. However, if muscle atrophy, particularly in the hypothenar area, is detected, surgery may be considered.[40-42]

Median Mononeuropathy

The median nerve arises from C5-T1 spinal nerve roots and exits the brachial plexus through the lower trunk (Fig. 107-6). Median mononeuropathy is usually diagnosed as carpal tunnel syndrome (CTS), which is the most common of all entrapment neuropathies. CTS has a prevalence of 3 to 6% in the U.S. population.[43] Although the patient may complain of bilateral symptoms, a careful history usually reveals that symptoms in one hand preceded those in the other. A common symptom of CTS is awakening at night and shaking the hand. Symptoms are often worsened by activity. For unclear reasons, the pain may spread as high as the arm or shoulder, although the paresthesias are generally confined to the fingers. Many patients on initial questioning state that their entire hand is involved, although this is not supported by careful sensory examination. Patients frequently note that their hands are clumsy or weak, especially when holding a glass or opening a screw-top container. The skin of the fingers innervated by the median nerve may be drier and rougher to the touch than the corresponding ulnar skin, depending on the duration of entrapment.

Box 107-6 Conditions Associated with Carpal Tunnel Syndrome

Acromegaly	Obesity
Amyloid	Pregnancy
Diabetes mellitus	Renal failure
Hypothyroidism	Rheumatoid arthritis

When motor involvement occurs in CTS, it is confined to the median intrinsics, which innervate the *l*umbricals (flexion of the metacarpophalangeal joints) and subserve thumb *o*pposition, *a*bduction, and *f*lexion, known as the LOAF muscles. However, the hallmark of CTS is sensory involvement, with motor abnormalities occurring later. The typical pattern of sensory innervation of the hand by the median, ulnar, and radial nerves shows marked individual variation. The most specific finding for CTS is splitting of the fourth digit (i.e., normal sensation of the ring finger on the ulnar palmar side with abnormal sensation on the median [radial] palmar side of the same finger). The most sensitive finding is abnormal sensation of the distal palmar tip of the index finger. If sensory findings are absent in the presence of motor findings consistent with median nerve involvement, it is highly unlikely that the patient has CTS, and an alternative diagnosis should be sought. Tinel's sign (percussion of the median nerve at the wrist) and Phalen's sign (maximal palmar flexion at the wrist) have been classically taught as provocative tests to reproduce the sensory symptoms of CTS if neither sensory nor motor symptoms are evident on initial examination. However, more recent evaluation has shown that Tinel's and Phalen's signs do not have adequate sensitivity or specificity to determine which patients should be referred for electrodiagnostic studies.[44] Dropping of objects is indicative of severe CTS.[45] As suggested earlier, the best way to examine patients for sensory findings is to touch the distal palmar tips very lightly, asking the patient whether the sensation feels "abnormal."

CTS appears to be associated with the conditions listed in Box 107-6. Of these, the two most common are diabetes mellitus and pregnancy.[46] CTS associated with systemic illness is commonly bilateral. Although CTS in pregnancy may be self-limited, about half the women in one series were still symptomatic at 1-year follow-up.[47] All patients with suspected CTS should be referred for NCSs. However, because of the dissociation between clinical and electrodiagnostic indicators of CTS early in the disease, patients with normal electrodiagnostic findings in the presence of symptoms suggestive of CTS (with or without signs) should have a magnetic resonance imaging (MRI) study or sonographic examination.[48] At present, the sensitivity of MRI is good but its specificity is poor.[49] Ultrasonography has been shown to be useful particularly in patients with symptoms and a normal NCS. This is done by measuring the cross-sectional area of the median nerve at the end of the pisiform.[50] Thus, if all diagnostic studies in a symptomatic patient have normal findings, or if only the MRI result is abnormal, they should be repeated within a few months if symptoms do not resolve. This recommendation is based on the theory that the CTS will progress over time to the point that an objective indicator, such as the NCS, will become positive.

www.ketabpezeshki.com 66485457-66963820

Steroid injection has been shown to be a temporizing measure in treatment of CTS.[51] Because of the possibility of a disabling "median hand" after inadvertent direct injection of the median nerve, it is recommended that emergency physicians defer the injection of the carpal tunnel with steroids to the consulting physician who will provide further care. This physician can decide after NCS whether to recommend splinting, injection, or surgical division of the transverse carpal ligament. Endoscopic repair appears to provide excellent results.[52,53] Noninvasive therapies in all cervicobrachial pain syndromes have yielded mixed results,[54] although smoking of cannabis has been found to improve chronic neuropathic pain.[55]

Sciatic Mononeuropathy

The sciatic nerve includes L4-S3 spinal nerve roots that pass through the lumbosacral plexus and divide into two terminal branches: the common peroneal and tibial nerves. The nerve exits the pelvis through the sciatic notch, passes behind the hip, and remains deep in the thigh until its terminal bifurcation in the proximal popliteal fossa (Fig. 107-7).

Lesions of the sciatic nerve occur with posterior hip dislocation or with virtually any form of penetrating or blunt trauma that causes formation of a buttock hematoma. Other causes include deep gluteal injection and prolonged supine immobilization on a firm surface. Because the sciatic nerve innervates the hamstrings and provides all sensorimotor function distal to the knee, a complete sciatic mononeuropathy is a devastating injury. Ambulation is extremely difficult because of inability to flex the knee and a flail foot (i.e., neither flexion nor extension is possible at the ankle). Fortunately, many sciatic mononeuropathies are incomplete. For unknown reasons, a partial lesion typically involves only the trunk of the sciatic nerve, which subsequently becomes the common peroneal nerve, sometimes making the two difficult to distinguish from one another clinically. On electrophysiologic studies, evidence of involvement of gluteal muscles or of any muscles innervated by the tibial nerve readily distinguishes a partial sciatic mononeuropathy from a lesion of the common peroneal nerve. Treatment of footdrop requires a posterior splint to maintain the ankle at 90 degrees until a brace can be obtained (see later section on common peroneal mononeuropathy).

Lateral Femoral Cutaneous Mononeuropathy

Lateral femoral cutaneous mononeuropathy (meralgia paresthetica) is a common syndrome believed to be caused by injury to this pure sensory nerve as it passes through or over the inguinal ligament, where it may become entrapped or kinked. Along with facial nerve neuropathy, meralgia paresthetica is one of the most commonly reported mononeuropathies associated with HIV infection. External pressure and obesity may also contribute to nerve injury, causing numbness and dysesthesia over the skin of the upper lateral thigh. Regression usually occurs spontaneously, but recurrence is common and may require a release procedure for the inguinal ligament.

Common Peroneal Mononeuropathy

The common peroneal nerve is a continuation of one trunk of the sciatic nerve. It is most vulnerable to injury where it winds around the fibular neck (Fig. 107-8). It then passes through the fibular canal and bifurcates into its terminal branches, the superficial and

www.ketabpezeshki.com 66485457-66963820

deep peroneal nerves. The superficial peroneal nerve innervates the peroneal muscles (foot everters) and supplies sensation to the lateral, distal lower leg and dorsum of the foot. The deep peroneal nerve traverses the anterior compartment and supplies innervation to the dorsiflexors of the foot and toes plus cutaneous sensation between the first and second toes.

Most common peroneal mononeuropathies are idiopathic and thought to be related to compression where the nerve is superficially located lateral to the fibular neck. Because this common neuropathy is often noted on awakening, it may be secondary to position during sleep. Leg crossing may also be a risk factor for development of this mononeuropathy. The most striking feature of a complete common peroneal mononeuropathy is footdrop caused by weakness of foot dorsiflexion. At testing, the everters of the foot are also weak, but the inverters, which are innervated by the tibial nerve, remain strong. This is the single most reliable clinical feature distinguishing sciatic from common peroneal mononeuropathy. Analogous to radial mononeuropathy in the upper extremity, sensory abnormalities in the leg and foot are inconstant and easily overlooked in peroneal mononeuropathy. Most patients with peroneal palsy recover. Those who do not should be studied electrophysiologically to ensure that the point of compression is not proximal to the fibular neck (i.e., in the popliteal fossa). If the point of peroneal injury appears to be in the region of or distal to the fibular neck on EMG, patients whose footdrop does not resolve should be considered candidates for exploration to determine whether the nerve is compressed within the fibular canal.

Treatment of common peroneal palsy may require a posterior splint to maintain the ankle at 90 degrees until the nerve regenerates. This splinting prevents the foot from falling into sustained equinus (plantar flexion), which in turn allows the intermalleolar distance to narrow, effectively locking the talus out of the ankle mortise.

The treatment of isolated mononeuropathies depends on their etiology, location, and natural history of spontaneous recovery. All penetrating neuropathies should have surgical exploration and repair performed. Blunt trauma may cause a mononeuropathy indirectly by entrapment of a nerve within a fracture, hematoma, or compartment, requiring surgical intervention. Alternatively, nerves may be injured at a point where they are superficial, either by a single direct blow or by sustained pressure caused by immobility (pressure palsies). Most of these resolve spontaneously over time, depending on the severity of injury and length of the nerve. If entrapment can be confirmed by imaging or electrophysiologic studies, a release procedure is indicated. The mononeuropathies that do not require timely surgical exploration should be referred for further workup to confirm the location of the neuropathic lesion.

Type 5: Mononeuropathy Multiplex

Mononeuropathy multiplex is characterized by an asymmetrical, sensorimotor, usually distal pattern of peripheral neuropathy (Box 107-7). As with isolated mononeuropathies, sensory abnormalities tend to be located in the same general anatomic region as the accompanying motor findings. Whether DTRs are affected depends on which nerves are involved. For example, if the process includes the femoral nerve, the patellar reflex is likely to be diminished or absent.

Vasculitis

Mononeuropathy multiplex is strongly associated with vasculitis, which is the most common indication for sural nerve biopsy in most series. However, because diabetes mellitus is far more prevalent than vasculitis, the most common cause of mononeuropathy multiplex among ED patients is diabetes.

Box 107-7 Mononeuropathy Multiplex

- Vasculitis
  - Systemic vasculitis
    - Polyarteritis nodosa
    - Rheumatoid arthritis
    - Systemic lupus erythematosus
    - Sjögren's syndrome (keratoconjunctivitis sicca)
  - Nonsystemic vasculitis
- Diabetes mellitus
- Neoplastic
  - Paraneoplastic
  - Direct infiltration
- Infectious
  - Lyme disease
  - HIV infection
- Sarcoid
- Toxic (lead)
- Transient (polycythemia vera)
- Cryoglobulinemia (hepatitis C)

Diabetes Mellitus

Although the role of ischemia in diabetic neuropathies is controversial, evidence for a vascular cause is stronger in the asymmetrical diabetic multiple mononeuropathies than in the more common DSPNs seen in diabetes.

Lyme Disease

The PNS manifestations of Lyme disease can be divided into early and late. The early PNS syndromes commonly include facial nerve involvement (rarely other cranial nerve palsies) and radiculoneuritis. Late PNS involvement occurs as a DSPN, mononeuropathy multiplex, or radiculoneuropathy. The most common neurologic abnormality in Lyme disease is unilateral or bilateral facial nerve palsy, usually occurring within a month of exposure. Patients may also complain of headache and constitutional symptoms. Early in the course of Lyme disease, severe neuritic pain may develop in a radicular distribution, often in or near the dermatome where the tick bite occurred. There may also be associated sensory changes, motor weakness, and decreased reflexes consistent with nerve root involvement. Patients with chronic Lyme disease present with sensory symptoms, particularly distal paresthesias in the lower extremities. Less commonly, they develop a picture consistent with mononeuropathy multiplex or a radiculopathy, which is much less severe than the early radiculoneuritis of Lyme disease.

The most useful diagnostic tests for patients with suspected Lyme disease are a serum enzyme-linked immunosorbent assay, Western blot, and CSF examination. CSF abnormalities suggestive of Lyme disease are a lymphocytic pleocytosis, elevated protein level, and normal glucose concentration. The CSF is almost always abnormal in early radiculitis, sometimes abnormal with isolated facial palsy, and typically normal in chronic Lyme disease. Facial nerve palsy without CSF abnormalities may be treated with oral doxycycline 100 mg twice a day for 2 weeks. Intravenous ceftriaxone is the drug of choice for all other neurologic syndromes associated with Lyme disease. The adult dosage is 2 g/day, and the pediatric dosage is 75 to 100 mg/kg/day. The standard course of treatment with intravenous ceftriaxone is at least 2 weeks.

www.ketabpezeshki.com 66485457-66963820

Type 6: Amyotrophic Lateral Sclerosis

Although *amyotrophic lateral sclerosis* (ALS) and *motor neuron disease* (MND) are often used synonymously, the latter represents a spectrum of diseases ranging from primary lateral sclerosis, in which degeneration is confined to upper motor neurons, to progressive muscle atrophy, in which only lower motor neurons are involved. ALS, which requires the presence of both upper and lower motor neuron findings, resides in the middle of this spectrum, representing the most common form of MND. The incidence of ALS is 1.5 to 2.5 per 100,000.[56]

In ALS, the primary pathologic process in the PNS component of the disease is a neuronopathy of the anterior horn cell. Because this structure is located proximal to the point where motor and sensory fibers merge to form mixed spinal nerve roots, the signs and symptoms of MND are purely motor (see Fig. 107-2). In the CNS, there is a loss of Betz cells from the motor cortex with secondary degeneration of the corticospinal tracts. Box 107-8 lists some representative upper, lower, and mixed motor signs. Patients typically demonstrate asymmetrical distal weakness without sensory findings. Positive motor phenomena in the form of fasciculations are found in almost all patients at diagnosis but are rarely an initial complaint. Although there is electrophysiologic evidence of autonomic involvement in ALS, this is generally subclinical.

Most patients with an asymmetrical, distal, pure motor neuropathy have ALS, for which only supportive treatment is currently available. However, there are some preliminary studies of recombinant human insulin-like growth factor 1 that have shown marginal improvement in this otherwise fatal disease.[57] All patients in whom this diagnosis is suspected should be referred for electrophysiologic confirmation against standardized criteria. Confirmation is particularly important because multifocal motor neuropathy, a rare disease that masquerades as ALS, responds dramatically to cyclophosphamide and immune globulin administration.

Type 7: Sensory Neuronopathy (Ganglionopathy)

This category of peripheral neuropathy is characterized by a selective or predominant involvement of the dorsal root ganglion,

Box 107-8 Objective Clinical Findings Consistent with Amyotrophic Lateral Sclerosis

Upper Motor Neuron Signs
- Hyperreflexia
  - Sustained clonus, especially at ankle
  - Finger flexors and jaw jerk
- Spasticity, especially of gait
- Presence of Babinski's sign

Lower Motor Neuron Signs
- Positive motor phenomena
  - Fasciculations
  - Cramps
- Negative motor phenomena
  - Asymmetrical distal weakness
  - Atrophy

Combined Upper and Lower Motor Neuron Signs
- Dysarthria
- Dysphagia
- Respiratory compromise

Box 107-9 Sensory Neuronopathies (Ganglionopathies)

- Herpes
  - Herpes simplex 1 and 2
  - Varicella-zoster (shingles)
- Inflammatory sensory polyganglionopathy
- Paraneoplastic
- Primary biliary cirrhosis
- Sjögren's syndrome (keratoconjunctivitis sicca)
- Toxin induced
  - Pyridoxine (vitamin B_6) overdose
  - Metals
    - Platinum (cisplatin)
    - Methyl mercury
- Vitamin E deficiency

Box 107-10 Ancillary Diagnostic Testing in Suspected Peripheral Neuropathy

Obtained in Most Patients
- Complete blood count
- Erythrocyte sedimentation rate
- Glucose
- Creatine kinase
- Creatinine

Obtained Only If Indicated
- Human chorionic gonadotropin
- Magnesium
- Phosphate
- Vitamin B_{12}
- Hemoglobin A_{1c}
- Serum protein electrophoresis with immune fixation electrophoresis
- VDRL (Venereal Disease Research Laboratory) or rapid plasma reagin screen with fluorescent treponemal antibody absorption test, as appropriate
- Thyroid function
- HIV titer
- Lyme enzyme-linked immunosorbent assay and Western blot
- Rheumatoid factor and antinuclear antibody
- Blood, urine, hair, or nails for metal, depending on suspected chronicity of exposure
- Specific serum antibodies to components of peripheral nervous system
- Cerebrospinal fluid for cells, protein, Lyme titer
- Electrodiagnostic testing
  - Nerve conduction studies
  - Electromyography
- Neurodiagnostic imaging
  - Magnetic resonance imaging
  - Computed tomography
  - Sonography
- Quantitative sensory testing
- Nerve biopsy
  - Sural
  - Intraepidermal nerve fiber density

www.ketabpezeshki.com 66485457-66963820

producing a relatively pure sensory syndrome analogous to the pure motor syndrome of ALS. Although all sensory modalities are affected, proprioception is profoundly altered, leading to sensory ataxia and loss of DTRs without weakness. The distribution is typically asymmetrical and distal at the outset, but depending on severity and extent of progression, it may become functionally symmetrical. Sensory ganglionopathies can now be confirmed by MRI of the spinal cord and surrounding areas, showing degeneration of central sensory projections that localize the disease process to the dorsal root ganglion.[58] Some of the more common causes of this type of peripheral neuropathy are listed in Box 107-9.

ANCILLARY DIAGNOSTIC TESTING

Relatively few blood tests contribute to the diagnosis of peripheral neuropathy, and only a small number of these are available in the ED. CSF analysis may be helpful in GBS and Lyme disease. Additional tests that may be indicated in patients referred for evaluation are listed in Box 107-10, along with others that may be ordered selectively, depending on the clinical picture. Expensive batteries of tests purporting to measure a wide variety of antibodies to components of peripheral neuropathies are commercially available but have not been shown to be useful as screening tests.

KEY CONCEPTS

- It is not usually possible to arrive at the diagnosis of a specific peripheral neuropathy in the ED because of the need for confirmatory ancillary testing. One should focus on identifying one of seven categorical patterns of peripheral neuropathy, shown in Figure 107-1 and listed in Table 107-1, after other non-PNS causes have been eliminated.
- One of these seven patterns can usually be identified by combining three clinical features that are readily obtainable from a goal-directed history and physical: (1) right-left symmetry or asymmetry, (2) proximal-distal location, and (3) sensorimotor modalities affected. This approach is summarized as an algorithm in Figure 107-1.
- Identification of one of the seven types of peripheral neuropathy determines the need for ancillary diagnostic testing, therapeutic intervention, disposition, and timing of neurologic referral.
- Respiratory compromise is the primary life-threatening event seen in some peripheral neuropathies; GBS is by far the most common peripheral neuropathic cause of respiratory arrest.
- Any patient with symmetrical weakness, distributed both proximally and distally, with loss or diminution of DTRs and variable sensory abnormalities should be treated as having GBS.

Chapter 108

Neuromuscular Disorders

Peter Shearer and Andy Jagoda

PERSPECTIVE

Disorders of the neuromuscular unit can result in clinical presentations that range from subtle symptoms to acute respiratory failure with significant morbidity and mortality. In most cases, the pathophysiologic mechanism of these disorders is well understood and permits an organization and understanding based on the level of the nervous system affected. This facilitates an approach that interprets signs and symptoms, the findings of which direct the urgency of diagnostic testing and treatment.

PRINCIPLES OF DISEASE

The neuromuscular unit has four components: the anterior horn cells of the spinal cord, the peripheral nerve, the neuromuscular junction, and the muscle innervated. The level of the pathologic process determines associated signs and symptoms (Table 108-1). *Myelopathies* involve the spinal cord; *radiculopathies* involve the nerve roots as they leave the spinal cord; *neuropathies* involve the peripheral nerves; and *myopathies* involve the muscle. The use of physical signs to differentiate these disorders is discussed in Chapter 13.

Neuropathies involve the axon or the myelin sheath of the nerve. Nerve conduction studies can differentiate the locations of involvement. As the conduction along the axon is disrupted, the subsequent delay in transmission first causes symptoms in the muscles controlled by longer nerve axons, resulting in a history of ascending weakness. As the myelin destruction or axonal degeneration progresses, patients usually note a slowly progressive course of symptoms.

The neuromuscular junction is composed of the presynaptic membrane, the postsynaptic membrane, and the synaptic cleft. The neurotransmitter is acetylcholine (ACh). The motor synapse is a nicotinic receptor, whereas muscarinic synapses link the central nervous system with the autonomic nervous system. Disorders of the postsynaptic nicotinic receptors produce weakness. Postsynaptic ACh receptors (AChRs) are continually turned over at a rate that is related to the amount of stimulation. A disorder of transmission often leads to increased production of AChRs. Myasthenia gravis (MG) is the prototype of neuromuscular junction diseases.

CLINICAL FINDINGS

History

The history of patients with complaints of weakness focuses on the acuity and progression of onset and the potential for airway compromise. Any complaint of difficulty in breathing or swallowing raises suspicion of bulbar involvement and concern for life-threatening deterioration. The history must elicit whether the weakness is muscle weakness or nonspecific generalized fatigue. Weakness is the inability to exert normal force, whereas fatigue implies a decrease in force with repetitive use. When muscle weakness exists, the clinician should determine whether it is focal or generalized, proximal or distal. The history of present illness should include the duration of symptoms, exacerbating and mitigating factors, and presence of associated symptoms such as fever, weight loss, and bowel or bladder changes.

Historical elements might explain the presenting complaint: a preexisting neuromuscular disorder that could lead to deterioration; prior episodes or a family history of weakness suggesting periodic paralysis; a recent respiratory or diarrhea illness suggesting a postinfectious, autoimmune process, such as transverse myelitis or Guillain-Barré syndrome (GBS); a cancer history suggesting a metastatic tumor as the cause of a compressive myelopathy; and a food or travel history suggesting botulism or tick exposure.

Physical Examination

The examination should first assess the patient's ability to breathe and ventilate and then evaluate the degree of weakness and the location of the lesion. The presence of swallowing and a strong cough suggest that the patient has sufficient protective and ventilatory reserve. The muscles used to lift the head off the bed may weaken before those of respiration and should be assessed. A patient who is not yet intubated but is complaining of shortness of breath or difficulty in breathing should have frequent measurements of forced vital capacity (FVC). Normal FVC ranges from 60 to 70 mL/kg; when the FVC reaches 15 mL/kg, ventilatory support is necessary. If vital capacity cannot be measured, a maximal negative inspiratory force (NIF) is easily determined. NIF of less than 15 mm Hg suggests the need for intubation. Blood gas analysis is not helpful because functional reserve can be severely diminished by the time a patient has either hypercarbia or hypoxia.

The assessment of vital signs is important because some causes of weakness may result in dysregulation of the autonomic system. A systematic neurologic examination assesses the patient's mental status, cranial nerves, motor function, sensory function, deep tendon reflexes, and coordination, including cerebellar function. The motor examination begins by determining whether the weakness is unilateral or bilateral and which muscle groups are involved. Key components of the examination include motor strength, muscle bulk, and presence of fasciculations. Box 108-1 provides the grading system used in motor strength assessment. Table 108-2 provides the findings used to distinguish upper motor neuron from lower motor neuron processes.

Table 108-1 Clinical Characteristics of Neuromuscular Diseases

DISEASE	HISTORY	STRENGTH	DEEP TENDON REFLEX	SENSATION	WASTING
Myelopathy	Trauma, infection, cancer	Normal to decreased	Increased	Normal to decreased	No
Motor neuron disease (ALS)	Progressive difficulty swallowing, speaking, walking	Decreased	Increased	Normal	Yes
Neuropathy	Recent infection Ascending weakness	Normal or decreased Distal > proximal	Decreased	Decreased	Yes
Neuromuscular junction disease	Food (canned goods) Tick exposure Easy fatigability	Normal to fatigue	Normal	Normal	No
Myopathy	Thyroid disease Previous similar episodes	Decreased Proximal > distal	Normal	Normal	Yes

ALS, amyotrophic lateral sclerosis.

Table 108-2 Distinguishing Upper Motor Neuron from Lower Motor Neuron Involvement

MOTOR NEURON	DEEP TENDON REFLEX	MUSCLE TONE	ATROPHY	FASCICULATIONS	BABINSKI'S RESPONSE
Upper motor neuron	Increased	Increased	No*	No	Present
Lower motor neuron	Decreased	Decreased	Yes	Yes	Absent

* Not significant but can occur.

Box 108-1 Grading Score for Motor Strength

5 = Normal strength
4 = Weak but able to resist examiner
3 = Moves against gravity but unable to resist examiner
2 = Moves but unable to resist gravity
1 = Flicker but no movement
0 = No movement

Differential Consideration

Myelopathies

Myelopathies are spinal cord disorders that are manifested with signs of upper motor neuron dysfunction, such as muscle weakness with increased spinal reflexes, including an extensor plantar reflex (Babinski's response). Muscle tone ranges from normal to slightly increased, eventually leading to spasticity. There may be bladder and bowel involvement. When sensory findings are present, they often define the level of the lesion. The presence of back pain suggests a compressive lesion, such as a herniated intravertebral disk, epidural hematoma, abscess, or tumor. Acute, painless spinal cord lesions include transverse myelitis and spinal cord infarction. Myelopathies are discussed in Chapter 106.

Motor Neuron Disease

The characteristic findings of motor neuron disease combine signs of both upper and lower motor neuron dysfunction, including hyperreflexia, muscle wasting, and fasciculations. Pain is not a component of the clinical picture. Amyotrophic lateral sclerosis, the prototypical motor neuron disease, is a progressive, incurable, neurodegenerative disorder of unclear etiology. It is most common in elders but is seen in people as young as 20 years. Patients may present with upper extremity, lower extremity, or bulbar weakness, which is often initially asymmetrical. The median survival time is 3 to 5 years; most patients ultimately succumb to respiratory failure.

Poliomyelitis affects the anterior horn cells and results in lower motor neuron disease without sensory involvement. The weakness can be symmetrical or more often asymmetrical. Patients initially have a clinical picture similar to that of viral meningitis, with fever and neck stiffness. Currently, most cases follow exposure of an immunocompromised host to the oral polio vaccine, and this should be sought in the history. The cerebrospinal fluid analysis resembles that of viral meningitis.

Neuropathies

Weakness from a neuropathy is often noted first in distal muscles and then ascends. Decreased grip strength and footdrop are common presentations. Muscle tone ranges from slightly diminished to flaccid, and deep tendon reflexes are diminished or absent. Patients exhibit varying degrees of altered sensation, muscle wasting, and fasciculations, depending on the duration of the symptoms. Disorders in the differential diagnosis include GBS, toxic neuropathies, diabetic neuropathy, and tick paralysis (which is caused by inhibition of both nerve conduction and function of the neuromuscular junction). Neuropathies are discussed in Chapter 107.

Diseases of the Neuromuscular Junction

Disorders of the neuromuscular junction cause motor fatigability. The initial depolarization at the nerve endplate stimulates a maximum number of AChRs on the muscle cell, producing a normal or nearly normal strength response. Repeated stimulation leads to diminishing motor strength, which is caused by one of three mechanisms: blockage of the receptors, as in MG; decrease in the amount of ACh released, as in botulism; or inactivation of ACh by irreversible binding, as in organophosphate poisoning.

A decrease in the release of ACh can cause a combination of nicotinic and muscarinic effects. The clinical manifestations of this are anticholinergic findings, such as decreased visual acuity, confusion, urinary retention, tachycardia, low-grade fever, and dry, flushed skin. In the case of Lambert-Eaton myasthenic syndrome, weakness is more pronounced at the beginning of muscle

www.ketabpezeshki.com 66485457-66963820

use and improves with repeated use as more ACh builds up in the synaptic cleft with each stimulation. Diseases of the neuromuscular junction are considered in patients who present with generalized weakness in association with an acute cranial nerve deficit. Muscle tone is generally diminished and sensation is preserved in diseases of the neuromuscular junction.

Myopathies

Myopathies produce generalized, symmetrical weakness. Reflexes are diminished, muscle tone is usually diminished, but sensation is preserved. Myopathies due to inflammatory disorders (polymyositis, dermatomyositis, polymyalgia rheumatica, and viral myositis) cause muscle pain and tenderness. Metabolic disorders affecting muscle strength (e.g., electrolyte and endocrine disorders) are painless in nature.

DIAGNOSTIC STRATEGIES

Laboratory Studies

Serum potassium, calcium, and phosphorus concentrations should be assessed in patients with acute weakness. Thyroid function tests are recommended in cases of suspected myopathies. A creatine kinase (CK) level assesses for muscle inflammation; urinalysis should be performed to test for the presence of myoglobinuria and possible rhabdomyolysis, and renal function studies should be obtained when rhabdomyolysis is present.

Special Studies

Magnetic resonance imaging is the preferred test for suspected cases of acute myelopathy. Computed tomography of the spinal cord with myelography can help differentiate compressive (herniation, abscess, tumor) from noncompressive causes when magnetic resonance imaging is not available. Cerebrospinal fluid analysis is indicated when GBS or transverse myelitis is suspected.

SPECIFIC DISORDERS

Disorders of the Neuromuscular Junction

Myasthenia Gravis

Perspective. MG affects approximately 60,000 Americans.[1] The age at onset is bimodal; women are most commonly affected between the ages of 20 and 40 years and men between 50 and 70 years. Whereas new cases of MG are occasionally diagnosed in the emergency department (ED), it is much more common for patients with established disease to present with exacerbations of their disorder, often caused by precipitating factors.

Principles of Disease. MG results from autoantibodies directed against the nicotinic AChR at the neuromuscular junction or from antibodies against muscle-specific tyrosine kinase. This leads to destruction of AChRs with a decrease in the total number of available receptors. The autoantibodies further compete with ACh for binding at remaining receptors. With repeated stimulation, fewer and fewer receptor sites are available for ACh binding, and fatigue develops.

Fatigability and muscle weakness are the hallmarks of MG. The clinical progression of MG is slow, and the likelihood of short-term complications is low, so the most important aspect of emergency care is early recognition and proper referral for further evaluation when the disease is suspected.

Clinical Features. Patients with MG present with easy fatigability as the result of progressive weakness with repeated activity of affected muscle groups. Ocular symptoms are often the first manifestation of MG; typical symptoms are ptosis, diplopia, and blurred vision. Ocular muscle weakness is the first sign in up to 40% of patients, although 85% of patients with MG eventually have ocular involvement. When ptosis is present, it is often worse toward the end of the day. Respiratory failure is rarely the initial symptom of MG. Even so, up to 17% of patients may have weakness of the muscles of respiration.[2] Bulbar muscles may be involved, producing dysarthria or dysphagia.

Lambert-Eaton myasthenic syndrome is a rare disorder. Almost 50% of cases are associated with small cell carcinoma of the lung. Autoantibodies cause inadequate release of ACh from nerve terminals, affecting both nicotinic and muscarinic receptors. With repeated stimulation, the amount of ACh in the synaptic cleft increases, leading to an increase in strength, the opposite of that seen with MG. The classic syndrome includes weakness that improves with use of muscles, particularly proximal hip and shoulder muscles; hyporeflexia; and autonomic dysfunction, most commonly seen as dry mouth.[3] Management primarily focuses on treatment of the underlying neoplastic disorder, although intravenous immune globulin (IVIG) has been reported to be useful.[4]

Diagnostic Strategies

New-Onset Myasthenia Gravis. The diagnosis of MG is based on clinical findings and a combination of serologic testing, electromyographic testing, and the bedside edrophonium or ice bag test. Serum testing for AChR antibodies is positive in 80 to 90% of patients with MG, but it is not available in the ED setting.

The edrophonium test and ice bag test are similar to perform, and the results are based on their effect on the ptosis seen in patients with suspected MG. The production of edrophonium was discontinued in early 2008, and it will no longer be available once current stores are depleted. Edrophonium is a short-acting acetylcholinesterase-blocking agent that produces an increase of ACh in the synaptic cleft and a reduction in ptosis after intravenous administration. With the ice bag test, cooling decreases symptoms in MG, whereas heat exacerbates symptoms. In both tests, the change in the amount of ptosis is measured before and after administration of edrophonium or application of an ice bag. The distance from the upper to the lower eyelid in the most severely affected eye is measured first. If edrophonium is given, an intravenous test dose of 1 to 2 mg is given first as some patients have a severe reaction. If no adverse reaction is found and the patient does not dramatically improve in 30 to 90 seconds, a second dose of 3 mg is given. If there is still no response, a final dose of 5 mg is given for a total maximum dose of 10 mg.[5] Atropine should be available at the bedside during the test. Because of the potential for cholinergic-induced increased airway secretions, this test should be used with caution in asthmatics and patients with chronic obstructive pulmonary disease. If an ice pack is used, it is applied to the affected eye for approximately 2 minutes, and the distance between the lids is measured again. A prospective evaluation of the ice bag approach found the test result to be positive (an improvement in distance of at least 2 mm) in 80% of patients with MG and no change in patients without MG.[6]

Myasthenic Crisis. Myasthenic crisis is defined as respiratory failure leading to mechanical ventilation. It occurs in 15 to 20% of patients with MG,[7] usually within the first 2 years of disease onset. Although it is potentially life-threatening, the mortality from this complication of MG has declined dramatically with aggressive care in the intensive care unit and the use of plasmapheresis or immunomodulatory therapy with high-dose IVIG and corticosteroids.

Crises are most often precipitated by underlying infection, aspiration, and medication changes, such as stopping anticholinergic

medications or taking a new medication that precipitates weakness. Other precipitants can be surgery and pregnancy (Box 108-2). A precipitant may not be identified in up to 30% of cases.[8]

The initial step in managing the patient in crisis is stabilization of the airway. Noninvasive ventilation with biphasic positive airway pressure may be effective in managing patients who need ventilatory support.[9]

All patients with MG who present to the ED should be assessed for signs of myasthenic crisis even when they do not complain of weakness. Many commonly used drugs can adversely affect patients with MG (see Box 108-2). A patient with stable MG who has an acute medical or surgical condition requires a full neurologic examination. The decision to admit or to discharge a patient with MG from the ED should take into account the potential for neurologic deterioration.

Management

Cholinesterase Inhibitors. Pyridostigmine (60-120 mg PO every 4-6 hours) and neostigmine (15-30 mg PO every 4-6 hours) prolong the presence and activity of ACh in the synaptic cleft. They are the backbone of chronic outpatient therapy and provide symptomatic improvement. The most common side effects are those of excessive cholinergic stimulation, such as increased airway secretions and increased bowel motility. At extremes, there may be bradycardia or even worsening of weakness, simulating a myasthenic crisis. These drugs are often used as adjunctive therapy to control symptoms while other therapy is being instituted, after which they are usually discontinued.[10] Cholinergic drug therapy, such as the intravenous administration of pyridostigmine, is not recommended for the treatment of myasthenic crises in the ED because plasmapheresis and IVIG are both safe and highly effective therapies.

Immunosuppressant Drugs. Immunosuppressant drugs are often used for the chronic control of MG. Although they have no role in the acute management of a myasthenic crisis, they may be started before extubation of a patient recovering from a crisis. Cochrane reviews in 2005 and 2007 found support for the use of corticosteroids but only limited evidence that cyclosporine, cyclophosphamide, and azathioprine improve MG.[11,12] Studies suggest that rituximab, a monoclonal antibody that decreases B-cell function, has an emerging role.[13] Of note, the initiation of corticosteroids in patients with moderate to severe weakness may actually precipitate a worsening of weakness or even myasthenic crisis.

Thymectomy. Whereas the association between thymoma and MG is not fully elaborated, it is well known that thymectomy for patients with thymoma can lead to remission of MG or enable a reduction in other medications. Thymectomy for patients with MG without thymoma has been shown to have similar benefits and is recommended by the American Academy of Neurology for patients younger than 60 years, with remission or improvement seen in up to 50% of cases.[14] The onset of improvement after thymectomy is often delayed for 2 to 5 years.

Immunomodulatory Therapy. Plasmapheresis and IVIG can be used for patients with exacerbations of MG or preoperatively in patients with stable MG.

Plasmapheresis removes the AChR antibodies and other immune complexes from the blood. The fall in AChR levels is associated with improvement in symptoms of MG. There is a risk of complications from hypotension or anticoagulation. Although there are no randomized controlled studies, a review yielded many case series with short-term benefit, especially in myasthenic crisis, and it is recommended by the American Academy of Neurology.[15]

A review of IVIG trials found one randomized controlled trial of IVIG versus placebo that demonstrated the benefit of IVIG. Another trial failed to show a difference between IVIG and plasmapheresis.[16] The decision to institute either therapy is based on the input of the consulting neurologist and the resources available at the admitting hospital. If plasmapheresis is not readily available for a patient with myasthenic crisis, IVIG should begin with 1 to 2 g/kg.

Botulism

Principles of Disease. Botulism is a toxin-mediated illness that can cause weakness leading to respiratory insufficiency. In 2009 the Centers for Disease Control and Prevention (CDC) reported 121 cases of botulism in the United States: 9% food-borne, 69% infant botulism, 19% wound botulism, and 3% unknown etiology. *Clostridium botulinum* is an anaerobic, spore-forming bacterium.[17] Three of eight known toxins produced by *C. botulinum* (types A, B, and E) cause human disease. There has been an increase in reported cases of wound botulism in Washington State, California, England, and Germany associated with injection drug use.[18] Botulism is also thought to be a potential agent for bioterrorism. The botulinum toxin works by binding irreversibly to the presynaptic membrane of peripheral and cranial nerves, inhibiting the release of ACh at the peripheral nerve synapse. As new receptors are generated, the patient improves.

Clinical Features. The botulinum toxin blocks both voluntary motor and autonomic functions. Because the disorder is at the neuromuscular junction, there is no pain or sensory deficit. The onset of symptoms is 6 to 48 hours after the ingestion of tainted food. There may or may not be accompanying signs and symptoms of gastroenteritis, with nausea, vomiting, abdominal cramps, diarrhea, or constipation. The classic feature of botulism is a descending, symmetrical, flaccid paralysis. Cranial nerves and bulbar muscles are affected first, causing diplopia, dysarthria, and dysphagia, followed later by generalized weakness. Because the toxin decreases cholinergic output, anticholinergic signs may be seen in the form of constipation, urinary retention, dry skin and eyes, and increased temperature. Pupils are often dilated and not reactive to light. This can be a point of differentiation from MG. Deep tendon reflexes are normal or diminished.

Infantile botulism results from the ingestion of *C. botulinum* spores that are able to germinate and produce toxin in the high pH of the gastrointestinal tract of infants. The same spores are not active in the gut of adults because of the lower pH. The CDC reports approximately 100 cases per year.[19] Botulism spores can survive in honey, so it is recommended that honey not be fed to infants. The clinical presentation includes constipation, poor feeding, lethargy, and weak cry; consequently, this diagnosis must be included in the differential diagnosis of the floppy infant.

Diagnostic Strategies. The diagnosis is made by both clinical findings and exclusion of other processes. The toxin can be identified in serum and stool, but the assay is not commonly available in most hospitals and requires a prolonged turnaround time.

www.ketabpezeshki.com 66485457-66963820

If the suspected food source is available, it should also be tested for the toxin.

Management. Treatment is initially focused on stabilization of the airway and supportive measures. In 2010 the CDC announced a new heptavalent botulinum antitoxin (HBAT) that is now the only antitoxin available in the United States for non-infant botulism. For suspected cases and to obtain HBAT, clinicians should contact their state health departments. The CDC also maintains a botulism duty officer at the CDC Emergency Operations Center (telephone, 770-488-7100).[20] An intravenous human botulism immune globulin (BabyBIG) has been developed for treatment of infantile botulism and is available through the California Department of Public Health Infant Botulism Treatment and Prevention Program on-call physician at 510-231-7600.[21]

Tick Paralysis

Principles of Disease. The pathogenesis of tick paralysis, also known as tick toxicosis, is not fully understood. It is known that a toxin, *ixovotoxin,* is injected while the tick feeds. The toxin appears to decrease the release of ACh at the neuromuscular junction and also reduces nerve conduction velocity. It may also have effects at autonomic ganglia, leading to pupillary signs. Colorado reports on average one case per year, although in 2006 four cases were reported during 1 week.[22]

Clinical Features. Tick paralysis is an acute, ascending, flaccid motor paralysis that can be confused with GBS, botulism, and MG. Symptoms usually begin 1 to 2 days after the female tick has attached and begun to feed, although delays of up to 6 days have been reported.[23] There may be associated ocular signs, such as fixed and dilated pupils, that can help distinguish it from GBS.

Management. The management is supportive care and tick removal. A tick can be removed by use of forceps to grasp it as closely as possible to the point of attachment. Care should be taken not to leave mouth parts in the patient's tissue. Although symptoms may resolve rapidly after removal of the tick, supportive measures such as intubation should not be withheld pending resolution of symptoms.

Disorders of the Muscles

Perspective

Newly acquired weakness originating at the muscle level can be divided into two types: inflammatory and toxic-metabolic. Inflammatory disorders usually produce pain and tenderness, whereas metabolic disorders do not.

Inflammatory Disorders

Principles of Disease. The most common inflammatory myopathies are polymyositis (PM) and dermatomyositis (DM). PM may be idiopathic in nature, occur secondary to infections (viral or bacterial), or be seen in conjunction with other disorders, such as sarcoidosis and hypereosinophilic syndromes. Inflammatory myopathies cause weakness, pain, and tenderness of the muscles involved.

Clinical Features. DM and PM can occur at any adult age, although DM may also affect children. There is a slightly increased incidence in women. They can be associated with various malignant neoplasms, such as of the breast, ovary, lung, and gastrointestinal tract, and lymphoproliferative disorders. Proximal muscle weakness predominates and leads to complaints of difficulty in rising from a seated position or climbing stairs and weakness in lifting the arms over the head. There is often pain and tenderness in these proximal muscles as well. There is a decrease in reflexes that is in proportion to the decrease in strength. Fasciculations are not seen, and atrophy is a very late finding.

DM is similar to PM, but it is also associated with classic skin findings. These are more prominent in childhood but are also found in adults. They include a periorbital heliotrope and erythema and swelling of the extensor surfaces of joints. The facial rash is usually photosensitive and may also involve the exposed areas of the chest and neck.

Diagnostic Strategies. Electrolyte abnormalities must be ruled out and the serum CK level checked. The CK level should be interpreted in light of the entire clinical picture; an elevated CK level does not establish the cause of weakness as a myopathy because some neuropathies can also produce an elevated CK level. Similarly, a normal CK level does not rule out a myopathy as the cause of weakness. Electromyography and muscle biopsy are used to confirm the diagnosis.[24]

Management. PM and DM are usually managed with oral prednisone in a dose of 1 to 2 mg/kg/day. When steroids prove ineffective and during acute exacerbations, cytotoxic drugs such as azathioprine and methotrexate are added. Fortunately, the degree of rhabdomyolysis seen with the inflammatory myopathies is not sufficient to cause renal impairment.

Metabolic Disorders

Perspective. Acute, generalized muscle weakness can be seen with a number of severe electrolyte abnormalities of any cause: hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hypomagnesemia, and hypophosphatemia. Acute painless myopathies can also be seen with endocrine disorders involving the thyroid, parathyroid, or adrenal glands.

Of particular interest are several disorders referred to collectively as the periodic paralyses, including familial periodic paralysis (FPP) of the hyperkalemic and hypokalemic forms and thyrotoxic periodic paralysis (TPP), which is similar to hypokalemic FPP except that it is associated with hyperthyroidism.

Periodic Paralysis

Principles of Disease. These are autosomal dominant disorders of ion channels resulting in intermittent attacks of flaccid extremity weakness associated with either hyperkalemia or hypokalemia, although hypokalemia is more common. Periodic paralysis is most often associated with an inherited genetic mutation. Patients usually report a personal and family history of similar episodes.[25]

Clinical Features and Diagnostic Strategies. Patients may suffer either isolated or recurrent episodes of flaccid paralysis. The lower limbs are involved more often than the upper, although both can be affected. Bulbar, ocular, and respiratory muscles are usually not involved. Onset is rapid; a prodrome of myalgias and muscle cramps may occur but is uncommon; mental status and sensory function are typically preserved, but reports of sensory nerve involvement have been documented.[26] Males are more often affected than females, and there is a higher incidence in Asians, particularly Japanese, although it occurs in other ethnic groups.

Attacks may be induced by the injection of insulin, epinephrine, or glucose. The onset of symptoms often follows a high carbohydrate intake (with subsequent insulin rise) and a period of rest. A typical complaint is acute weakness noted on waking the morning after a large meal. The electrocardiogram may demonstrate signs of hyperkalemia or hypokalemia. An immediate determination of potassium level should be obtained; in the hypokalemic form, the potassium level during an attack falls to values below 3.0 mEq/L.

Management. Many cases resolve spontaneously with supportive care alone. The mainstay of management is the treatment of the underlying electrolyte imbalance. In the hypokalemic state, the total body potassium concentration is not depleted but has

www.ketabpezeshki.com 66485457-66963820

shifted intracellularly. Thus, in the repletion of potassium, caution is necessary to prevent overtreatment. For this reason, intravenous potassium should be used sparingly; one or two 10-mEq doses of potassium chloride, during 1 hour, is the maximum intravenous dose. This can be done in parallel with 40 mEq oral potassium repletion and retesting of serum potassium levels. Intravenous hydration helps redistribute the body's potassium stores.

Thyrotoxic Periodic Paralysis. The clinical picture of TPP is almost identical to that of hypokalemic FPP, and indeed a small number of patients with hypokalemic FPP have hyperthyroidism. In TPP, symptoms related to hyperthyroidism are often present at the same time the patient has weakness. The relation of the hyperthyroidism to hypokalemia is probably due to increased sodium-potassium–adenosine triphosphatase activity, which causes a rapid shift of potassium from the extracellular into the intracellular compartment. Treatment of the hyperthyroid symptoms, such as tachycardia, may help the paralysis as well. There are case reports of TPP in which the patient's weakness did not respond to potassium replacement until propranolol was given to treat tachycardia.[27,28] There is probably a genetic feature underlying this disorder because there is a higher incidence of repeated attacks of hypokalemic periodic paralysis among Japanese and Chinese patients with hyperthyroidism. It is important that all patients have thyroid function testing performed after a first episode of hypokalemic paralysis.

KEY CONCEPTS

- The approach to evaluation of patients with acute neuromuscular weakness is facilitated by first determining the location of the lesion (spinal cord, nerve, neuromuscular junction, or muscle) and then considering the most common disorders that affect the area in question.
- In patients with bilateral upper motor neuron signs and a normal mental status, neuroimaging of the spinal cord should be strongly considered.
- In patients presenting with acute neuromuscular weakness, complaints of difficulty in breathing or swallowing should heighten suspicion of bulbar involvement with possible airway compromise. In such patients, FVC of less than 15 mL/kg or maximal NIF of less than 15 mm Hg is a potential indication for mechanical ventilation.
- Botulism usually arises as a painless descending paralysis, often first affecting the cranial nerves and bulbar muscles, without sensory deficits or significant alteration of consciousness. The treatment is airway management and administration of antitoxin.

Chapter 109

Central Nervous System Infections

William J. Meurer

PERSPECTIVE

Background

Central nervous system (CNS) infections have always been among the most perplexing and devastating illnesses. "Epidemic cerebrospinal fever," classically described by Vieusseux in 1805, was associated with almost universal mortality.[1] The first American epidemic of meningococcal meningitis was recorded in 1806.[2] Since that time, epidemiologic changes have occurred in concert with advances in understanding of disease processes and evolution of effective treatment strategies.

The etiologic spectrum of CNS infection has changed considerably as a result of the development and aggressive use of antibiotics and the epidemic emergence of diseases and conditions that impair the immune system, such as infection with the human immunodeficiency virus (HIV). Some of the research on CNS infections at the cellular and molecular levels has provided insights into pathogenesis, including the role of host mechanisms such as cytokines and other immune components.

Likewise, diagnostic tools have been developed that allow precise pathogen identification, most recently by molecular technologies such as polymerase chain reaction (PCR) tests for viral nucleic acids in cerebrospinal fluid (CSF). The initial treatment methods began by demonstrating the efficacy of antiserum treatment by Flexner in 1913 and of antibiotics by Colebrook and Kenny in 1936.[3,4] Mortality rates in CNS infections were decreased further with the use of high-dose penicillin by Dowling and colleagues in the 1940s.[5] Unfortunately, despite historical advances, the morbidity and mortality of these disorders remain considerable.[6] The use of pneumococcal, *Haemophilus influenzae* type b, and meningococcal vaccines has led to dramatic reductions in the incidence of meningitis caused by these bacteria.[7-10]

Definitions

CNS infections comprise a broad spectrum of disease entities. *Meningitis* is defined as inflammation of the membranes of the brain or spinal cord and is also called *arachnoiditis* or *leptomeningitis*. *Encephalitis* denotes inflammation of the brain itself, whereas *myelitis* refers to inflammation of the spinal cord. The terms *meningoencephalitis* and *encephalomyelitis* describe more diffuse inflammatory processes. Collections of infective and purulent materials may form within the CNS as abscesses. Brain abscesses may be intraparenchymal, in epidural or subdural intracranial locations, or may be found in intramedullary or epidural spinal locations.

This chapter focuses on the more common acute and subacute CNS infections. Infections of the nervous system with HIV or human T-lymphotropic virus, rabies virus, poliovirus, hepatitis viruses, *Borrelia burgdorferi* (Lyme disease), *Treponema* organisms (syphilis), parasites, or *Rickettsia* and the chronic and slow infections of the CNS (subacute sclerosing panencephalitis; progressive multifocal leukoencephalopathy; and the prion-mediated spongiform encephalopathies, such as Creutzfeldt-Jakob disease, bovine spongiform encephalopathy, and kuru) are not addressed in detail. Of note, the incidence of neurocysticercosis is on the rise in the United States.[11]

Epidemiology

Bacterial meningitis is a common disease worldwide. Meningococcal meningitis is endemic in parts of Africa, and epidemics commonly occur in other countries, including the United States. A variety of other pathogens are also causative.[12-16] The overall incidence of bacterial meningitis in the United States is 5 to 10 cases per 100,000 people per year.[17] Men are affected more often than women are.[17] Approximately 80% of cases in the United States are caused by either *Streptococcus pneumoniae* or *Neisseria meningitidis*.[18] In regions where vaccination is common, the epidemiology of bacterial meningitis has substantially changed.[7-10,19] The incidence of bacterial meningitis increases in late winter and early spring, but the disease may occur at any time of the year.

Because most cases go unreported, the actual incidence of viral meningitis is unknown. It is estimated to affect between 11 and 27 individuals per 100,000 people.[20] A prominent increase of cases is seen in summer months, which is concurrent with seasonal predominance of the enterovirus group of the picornaviruses.

The same organisms responsible for viral meningitis may also be associated with encephalitis. Encephalitis is far less common, however, and the ratio of cases of meningitis to encephalitis varies according to the specific pathogen. Arbovirus infection is transmitted by an insect vector, although clinical disease develops in only a small percentage of the people bitten. Before 1999, there were approximately 19,000 hospitalizations in the United States annually for cases of encephalitis. Since then, there has been a rapid increase because of emergence of West Nile virus (WNV). In 2003, more than 8000 additional hospitalizations were required because of WNV alone.[21,22]

Approximately 2000 cases of brain abscess occur in the United States annually.[23] Although CNS abscesses may occur at any age and any time of year, they are seen more commonly in men than in women.[24] CNS abscesses are associated with local contiguous and remote systemic infections, injection drug use, neurologic surgery, and cranial trauma. Brain abscess secondary to otitis media most often occurs in pediatric or older adult populations. When brain abscess is associated with sinusitis, it most often arises among young adults. Increasingly, CNS abscesses are seen

www.ketabpezeshki.com 66485457-66963820

in immunocompromised patients, particularly those with HIV infection, and among bone marrow and solid organ transplant recipients. However, antimicrobial prophylaxis of immunosuppressed patients and more aggressive treatment of otitis and sinusitis have decreased the overall incidence to 0.9 per 100,000 person-years.[23]

PRINCIPLES OF DISEASE

Etiology

Meningitis

Meningeal inflammation may be caused by a variety of disease processes, but the infectious causes predominate. Among the bacterial agents, *Streptococcus pneumoniae* remains the predominant pathogen in adult patients, followed by *Neisseria meningitidis* and *Listeria monocytogenes*.[25] *N. meningitidis* is the predominant organism in adults younger than 45 years. Five major serogroups cause most meningococcal disease worldwide (A, B, C, Y, and W-135). Serogroup A accounts for the majority of cases of meningococcal meningitis in developing nations.[26] A new vaccine for serogroup A may potentially reduce the impact of this disease in nearly half a billion individuals at risk.[27] Serogroup distribution for invasive disease has changed markedly in the United States, with B, C, and Y now most commonly responsible.[28] These pathogens account for the bulk of cases in nontraumatic meningitis, although virtually any organism can be encountered, particularly among patients who are elderly, alcoholic, or immunosuppressed and those who have cancer. Interestingly, higher case fatality has been observed in *N. meningitidis* outbreaks versus sporadic cases, probably because of increased virulence of outbreak-related strains.[29] Causes of aseptic meningitis, simply defined as all cases with CSF cultures negative for bacteria, are listed in Box 109-1.[30]

Meningeal infection may also occur in association with a dural leak secondary to neurosurgery or neurotrauma. *S. pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa*, and coliform bacteria are seen most commonly in this population.

Viral meningitis may likewise be caused by a variety of etiologic agents.[31] Enteroviruses are statistically encountered most commonly.[32] Unfortunately, precise identification of the etiologic agent is often impossible. Fungal and parasitic meningitides are additional concerns, particularly among immunocompromised patients.[14,15] Viral meningitis secondary to herpes simplex virus (HSV) infection is actually relatively benign, especially in comparison with HSV encephalitis.[33]

Noninfectious meningitides include drug-induced meningitis, carcinomatous meningitis, CNS involvement in serum sickness, vasculitis, systemic lupus erythematosus, Behçet's disease, sarcoidosis, and others. The differentiation of noninfectious from infectious causes can often be perplexing.

Encephalitis

Arboviruses and HSV, a human herpesvirus (HHV), are the most common causes of epidemic and sporadic cases of encephalitis, respectively. Children are the most vulnerable to infection with these viruses, although adults are also commonly affected. Epidemics of viral encephalitis have been attributed to a wide variety of viral agents. WNV, a flavivirus, first infected humans in the New York City area and rapidly spread to 47 states by 2003.[15,34] Varicella, herpes zoster, HHV types 6 and 7, and Epstein-Barr virus have been increasingly reported to be the cause of encephalitis in immunocompetent hosts.[35] Vaccinia encephalitis has been recognized in those receiving vaccination for smallpox.[36] Postinfectious encephalomyelitis is also induced by a variety of viral pathogens, most commonly the measles virus.[37] However,

Neoplastic disorders
- Leukemia
- Carcinomatous meningitis secondary to primary or secondary tumors of the brain

Inflammation of neighboring structures
- Brain abscess
- Epidural abscess

Miscellaneous
- Arachnoiditis
- Migraine
- Urinary tract infection

From Kumar R: Aseptic meningitis: Diagnosis and management. Indian J Pediatr 72:57-63, 2005.

Mycoplasma pneumoniae and idiopathic causes are becoming more common in developed countries.

Central Nervous System Abscess

The causes of CNS abscess are multiple and reflect the primary infective process and the immune state of the human host. A variety of mixed pathogens may be responsible for intracranial abscesses. Streptococci, particularly the *Streptococcus milleri* group, have been identified in nearly 50% of brain abscesses.[38] Anaerobic

www.ketabpezeshki.com 66485457-66963820

Figure 109-1. Central nervous system abscess: computed tomography scan of an intraparenchymal abscess (*arrows*).

bacteria, predominantly *Bacteroides* species, are commonly seen when the primary infectious process is chronic otitis media or pulmonary disease. *S. aureus* and *Propionibacterium* are often identified, particularly after cranial penetration from surgery or trauma.[39] The Enterobacteriaceae are an additional common isolate. Opportunistic fungal and parasitic agents, including *Nocardia* species, are often seen in the immunosuppressed.[40] Culture of epidural and subdural abscesses more often yields a single organism; streptococci are most commonly seen in association with contiguous spread, and *S. aureus* and gram-negative rods are most commonly encountered after neurologic trauma (Fig. 109-1).[15] Etiologic agents in spinal abscess are similarly varied, with *S. aureus* being the most commonly encountered.

Pathophysiology

Bacterial Meningitis

The pathogenetic sequence in bacterial meningitis has been well characterized.[14,15] The first step is nasopharyngeal colonization and mucosal invasion. Although colonization rates vary, virulent microbes use secretion of immunoglobulin A proteases and induce ciliostasis of mucosal cells. After penetration occurs by a variety of mechanisms, bacterial intravascular survival occurs because of evasion of the complement pathway. The varying capsular properties of each organism protect the bacteria. The third step occurs when the bacteria cross the blood-brain barrier to enter the CSF. The dural venous sinuses, cribriform plate area, and choroid plexus have all been implicated as potential sites of invasion. Although the mechanism of invasion is not completely understood, host defense mechanisms within the CSF are often ineffective; there are low levels of complement, immunoglobulin, and opsonic activity. Bacterial proliferation then occurs, which stimulates a convergence of leukocytes into the CSF.

Meningeal and subarachnoid space inflammation is also associated with the release of cytokines into the CSF, most notably tumor necrosis factor and interleukins 1 and 6.[41] This results in increased permeability of the blood-brain barrier, cerebral vasculitis, edema, and increased intracranial pressure. A subsequent decrease in cerebral blood flow leads to cerebral hypoxia. Glucose transport into the CSF is decreased concomitantly with an increased use of glucose by the brain, bacteria, and leukocytes, which depresses CSF glucose concentrations. The increased permeability leads to increased CSF proteins.

Viral Meningitis and Encephalitis

Viruses enter the human host through the skin (i.e., insect vectors); through the respiratory, gastrointestinal, or urogenital tract; or by receipt of infected blood products or donor organs.[42] Viral replication subsequently occurs outside the CNS, most often followed by hematogenous spread to the CNS. Additional routes into the CNS include retrograde transmission along neuronal axons and direct invasion of the subarachnoid space after infection of the olfactory submucosa.[43,44]

Fortunately, most systemic viral infections do not result in meningitis or encephalitis. The development and subsequent magnitude of viral infection depend on the virulence of the specific virus, the viral inoculum level, and the state of immunity of the human host. The tropism of the virus for specific CNS cell types also influences the focality of disease and its manifestations.[43] Particular viruses may preferentially attack cortical, limbic, or spinal neurons, oligodendroglia, or ependymal cells. An example is the tropism of HSV for the temporal lobes and the development of temporal lobe seizures and behavioral changes in afflicted patients.

Fungal Meningitis

Fungal meningitis probably develops in much the same way as bacterial meningitis does, although this has been incompletely studied. Pulmonary exposure followed by hematogenous spread is the primary pathogenic mechanism in most cases. Immune system defects or immunosuppressive medications compromise host defense mechanisms, with ensuing development of CNS infection.

Central Nervous System Abscess

Intraparenchymal brain abscesses, subdural empyema, and intracranial or spinal epidural abscesses form by inoculation of the CNS from contiguous spread of organisms from a sinus, middle ear, or dental infection or metastatic seeding from a distant site, usually from pulmonary infection, endocarditis, or osteomyelitis.[45] The primary infection can be identified in 75 to 85% of cases. These conditions may also follow surgery or penetrating cranial trauma, particularly when bone fragments are retained in brain tissue. Otogenic abscesses occur most commonly in the temporal lobe in adults and the cerebellum in children, whereas sinogenic abscesses typically occur in frontal areas.[38] Multiple brain abscesses suggest hematogenous spread of organisms, although solitary lesions may also occur. The pulmonary system is the most common source of hematogenous spread.[15]

CLINICAL FEATURES

Symptoms and Signs

Numerous host factors have been implicated in the acquisition of meningitis (Box 109-2).[46] Although these factors alone and in combination increase the risk of meningitis, the disease often occurs in patients with none of these factors.

Many patients with meningitis present with advanced disease; in these patients, the diagnosis of acute meningitis is strongly

www.ketabpezeshki.com 66485457-66963820

Box 109-2 Host Factors Predisposing to Meningitis

Age < 5 years

Injection drug abuse
Bacterial endocarditis
Ventriculoperitoneal shunt
Malignant disease

suspected. The constellation of symptoms that may classically occur in an acute CNS infection consists of fever, headache, photophobia, nuchal rigidity, lethargy, malaise, altered sensorium, seizures, vomiting, and chills.[13,46]

Unfortunately, more subtle presentations are also common. Immunosuppressed and geriatric patients present a diagnostic challenge because the classic signs and symptoms of meningitis may not be present. Although some degree of fever is present in most patients, as are a headache and neck stiffness, meningitis should be carefully considered in any immunosuppressed patient with symptoms or signs of infectious disease. Often, the only presenting sign of meningitis in elders is an alteration of mental status. However, a meta-analysis suggested that the absence of fever, stiff neck, and mental status change excludes meningitis in immunocompetent adults.[47] A systematic review of prospective data in children found several clinical factors that were useful in influencing the likelihood of bacterial meningitis within suspected cases.[48] There was no combination of factors that could rule in or rule out the disease, which is not surprising given the diversity of presentations in children.

The presentation of fungal meningitis can be obscure even in the healthy adult population. Headache, low-grade fever, lassitude, and weight loss may be present but often to such a mild degree that the correct diagnosis is not initially considered.[13] This is also true of tuberculous meningitis, which often has a protracted course and a vague nonspecific presentation consisting of fever, weight loss, night sweats, and malaise, with or without headache and meningismus.[12]

The physical findings in meningitis vary by the host, causative organism, and severity of the illness. Nuchal rigidity or discomfort on flexion of the neck is common. Kernig's sign (the inability to straighten the leg to a position of full knee extension when the patient is lying supine with the hip flexed to a right angle) and Brudzinski's sign (attempts to flex the neck passively are accompanied by flexion of the hips) are present in approximately 50% of adults.[15] In the evaluation of patients with suspected meningitis, the sensitivity of Kernig's sign, Brudzinski's sign, and nuchal rigidity are 5%, 5%, and 30%, respectively, suggesting that these physical examination findings have little diagnostic value.[49] Deep tendon reflexes may be increased, and ophthalmoplegia may be present, especially of the lateral rectus muscles.

The systemic findings may include an obvious source of infection, such as sinusitis, otitis media, mastoiditis, pneumonia, or urinary tract infection. Various manifestations of endocarditis may be present. Arthritis may be seen with *N. meningitidis* and occasionally with other bacteria.[46] Petechiae and cutaneous hemorrhages are widely reported with meningococcemia but also occur with *H. influenzae* type b, pneumococcal organisms, *L. monocytogenes,* and ECHO virus infections in addition to staphylococcal endocarditis.[46] Endotoxic shock with vascular collapse often develops in severe meningococcal disease, but shock may be present in the advanced stages of any bacterial meningitis. Any determination of a serious systemic infection should encourage rather than dissuade the clinician from considering the possibility of a concomitant CNS infection.

Patients with encephalitis may also have symptoms of meningeal irritation. An alteration of consciousness occurs in virtually all patients. Fever, headache, and a change of personality are also usually present.[44] Hallucinations and bizarre behavior may precede motor, reflex, and other neurologic manifestations by several days, occasionally prompting an initial diagnosis of a psychiatric disorder. Because focal neurologic deficits and seizures occur much more commonly with encephalitis than with meningitis, there may also be diagnostic confusion with a brain abscess. It is difficult to distinguish the etiologic agent in encephalitis clinically, although HSV encephalitis results in a higher incidence of dysphasia and seizures.[50] In some patients, WNV produces a myelitis that affects the anterior horn cells of the spinal column, resulting in a flaccid paralysis with a clear sensorium, similar to findings in poliomyelitis or Guillain-Barré syndrome.[34]

Patients with intracranial abscess may be indistinguishable from those with meningitis or encephalitis. Most patients with intraparenchymal abscess have a subacute course of illness, with symptoms progressing during the course of 2 weeks or more. However, nuchal rigidity and fever are present in less than 50% of cases. Focal neurologic deficits are present in most of these patients. A large number of patients exhibit papilledema, which is a rare finding in meningitis. An abrupt neurologic deterioration that results from uncal herniation or rupture into the ventricular system may occur.

Patients with a subdural or epidural abscess most often have headache, fever, and focal signs, although more subtle presentations are common. Most of the patients with spinal abscess typically present with spinal pain and other symptoms and signs of cord compression but not necessarily with fever.[51]

Complications

Bacterial Meningitis

The immediate complications of bacterial meningitis include coma (with loss of protective airway reflexes), seizures, cerebral edema, vasomotor collapse, disseminated intravascular coagulation, respiratory arrest, dehydration, syndrome of inappropriate secretion of antidiuretic hormone, pericardial effusion, and death (Box 109-3).[16] Various delayed complications include multiple seizures, focal paralysis, subdural effusions, hydrocephalus, intellectual deficits, sensorineural hearing loss, ataxia, blindness, bilateral adrenal hemorrhage (Waterhouse-Friderichsen syndrome), peripheral gangrene, and death.[46]

The case fatality rate for pneumococcal meningitis averages 20 to 25%; higher fatality rates occur in patients with serious underlying or concomitant disease or advanced age.[52] The prognosis is related to the degree of neurologic impairment on presentation. Overall, 20 to 30% of the survivors of pneumococcal meningitis have some residual neurologic deficit.[46] The case fatality rate for *Listeria* meningitis may be as high as 40%.[25]

With the advent of antibiotic therapy, the mortality from meningococcal meningitis has markedly decreased to less than 20%, but it remains substantially higher in elders and those who

have meningococcemia.[52] Although most of the complications and sequelae are less common than with pneumococcal disease, the incidence of Waterhouse-Friderichsen syndrome is dramatically higher when meningococcemia is present.[46] The overall mortality rate in community-acquired gram-negative meningitis has been less than 20% since the introduction of the third-generation cephalosporins.[14] Hydrocephalus may develop in as many as 5% of patients with community-acquired meningitis; when this is present on admission, the proportion dead or with an unfavorable outcome approaches 50 to 70%.[53] A delayed cerebral venous thrombosis was observed in several adults with an initially excellent recovery from pneumococcal meningitis, suggesting an immunologic vasculopathy.[54]

Viral Meningitis

With rare exceptions, the overall prognosis for complete recovery from viral meningitis is excellent. Various complications related to the systemic effects of the particular virus include orchitis, parotitis, pancreatitis, and various dermatoses. Usually, all of these complications resolve without sequelae.[31] Interestingly, HSV meningitis is often associated with the initial outbreak of genital herpes.[33]

Viral Encephalitis

The outcomes in viral encephalitis are dependent on the infecting agent. Encephalitis caused by Japanese encephalitis virus, Eastern equine virus, and St. Louis encephalitis virus is severe, with high mortality rates and virtually universal neurologic sequelae among survivors.[55] WNV produces encephalitis in only 0.5% of those infected, yet it resulted in 120 deaths in 2003.[22] Western equine virus and California encephalitis virus cause milder infections, and death is rare. The incidence of neurologic sequelae is highly variable and appears to depend on both the host and the infecting agent.[56] Reports have emerged of influenza A H1N1 encephalitis that bears striking resemblance to "encephalitis lethargica," reported as a complication of influenza-like illnesses in the 1920s.[57]

The mortality from HSV encephalitis before the use of acyclovir was 60 to 70%. Acyclovir treatment has reduced the mortality to approximately 30%.[37] Common complications observed among survivors include seizure disorders, motor deficits, and changes in mentation.

Tuberculous Meningitis

Death from tuberculous meningitis in the adult age group ranges from 10 to 50% of cases, with the incidence directly proportional to the patient's age and the duration of symptoms before presentation. Focal ischemic stroke may result from the associated cerebral vasculitis. In advanced disease, up to 25% of patients may require some neurosurgical procedure for obstruction (ventriculoperitoneal shunt or drainage).[58] Some neurologic deficit develops in most patients, but severe long-term sequelae among survivors are unusual.[12]

Fungal Meningitis

Common CNS complications with fungal meningitis include abscesses, papilledema, neurologic deficits, seizures, bone invasion, and fluid collections. Direct invasion of the optic nerve results in ocular abnormalities in up to 40% of patients with cryptococcal meningitis.[13] The mortality rate is high but variable and is related to the timeliness of diagnosis, underlying illness, and therapeutic regimens.

Central Nervous System Abscess

With the early diagnosis afforded by the use of cranial computed tomography (CT), appropriate antimicrobial therapy, and combined management approaches with surgery, aspiration, and medical therapy, the mortality rate from brain abscess has declined dramatically from approximately 50% to less than 20%.[45,59] A seizure disorder is the most common complication of an intracranial abscess, occurring in 80% of patients.[14] Other neurologic findings of intracranial abscesses, including focal motor or sensory deficits and changes in mentation, are common. Complications of spinal abscess primarily result from cord compression, including paralysis, motor and sensory deficits, and bowel and bladder dysfunction. Generalized spread of CNS infection and death may also occur.[51]

DIAGNOSTIC STRATEGIES

Lumbar Puncture

General Considerations

The possibility of the diagnosis of meningitis mandates lumbar puncture (LP) unless the procedure is contraindicated by the presence of infection in the skin or soft tissues at the puncture site or the likelihood of brain herniation.[37] Adherence to this principle prevents a delay in diagnosis, which substantially increases the morbidity and mortality of the disease. Some patients have clinically obvious bacterial meningitis, and CSF examination serves primarily to help identify the organism, thereby facilitating the appropriate treatment. Most patients, however, present more of a diagnostic problem, and analysis of the CSF constitutes the critical step in confirming the presence of CNS infection.

Increased Intracranial Pressure

In most patients with bacterial meningitis, LP may be safely performed without antecedent neuroimaging studies. As this may not be the case in other brain diseases, in many circumstances it is advisable to obtain a CT scan of the head before LP is performed.[60]

www.ketabpezeshki.com 66485457-66963820

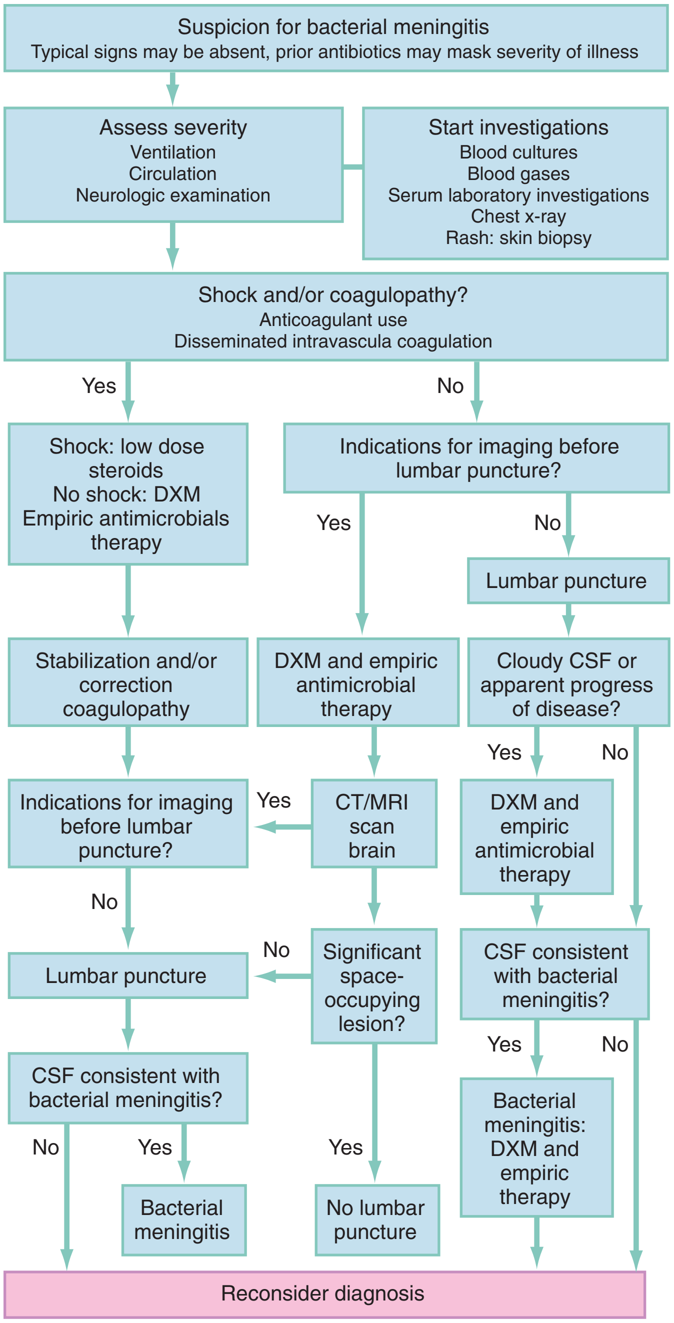

Figure 109-2. Algorithm for diagnostic and therapeutic decision-making when bacterial meningitis is clinically suspected. *CSF,* cerebrospinal fluid; *CT,* computed tomography; *DXM,* dextromethorphan; *MRI,* magnetic resonance imaging.

An algorithm for diagnostic and therapeutic decision-making is presented in Figure 109-2.[61]

It has been conventionally asserted that LP in the presence of increased intracranial pressure may be harmful or fatal to the patient. Although data to address this concern are limited, the presence of focal neurologic signs does appear to be associated with a dramatic increase in complications associated with LP. These patients may deteriorate precipitously during or after the procedure.[62-65]

Patients with a markedly depressed sensorium that precludes careful neurologic examination or those with a focal neurologic deficit, papilledema, seizures, or evidence of head trauma must be considered to be at risk for a herniation syndrome that may be exacerbated by LP. If the presentation is an acute, fulminating, febrile illness and bacterial meningitis is the concerning diagnosis, early initiation of antimicrobial therapy is mandatory because of the association of prognosis and time to treatment.[66] The algorithmic alternatives are therefore (1) immediate LP followed by initiation of antibiotic treatment before the results are obtained and (2) initiation of antibiotic treatment followed by a cranial CT scan and then LP. The latter choice of empirical treatment with antibiotics is now the routine in many institutions, although in some cases a third option could be considered: antibiotics and no LP despite an unremarkable CT scan.[65] This reflects the efficacy of current methods of identification of causative organisms in CSF by means other than bacteriologic cultures that are less likely to be affected by antibiotic administration. The controversy emerging about not performing LP despite a lack of CT findings is based on some reviews and case reports. These describe a fulminant herniation syndrome temporally related to LP in patients with normal CT scans.[63] Raised intracranial pressure may not be reliably detected by CT. Clinical signs of increased intracranial pressure, rapid change in consciousness, and recent seizures were identified as risk factors predicting deterioration despite a normal CT scan.[65] The risks of ongoing empirical treatment with antibiotics without additional information from CSF analysis appears to be low as the yield from blood cultures and other diagnostic techniques such as PCR is relatively high. Therefore, this risk may be less than the risks of performing LP in certain very high-risk patients. In patients who have rapid neurologic deterioration, seizures, or signs of herniation, antibiotics should be given, a CT scan ordered, and the patient moved to intensive care. In this situation, LP may be deferred.

Cerebrospinal Fluid Analysis

Opening Pressure

The normal CSF pressure in an adult varies from 5 to 20 cm H_2O. This value applies only to patients in the lateral recumbent position and may increase substantially when the patient is in the sitting position. The pressure is often elevated in bacterial, tuberculous, and fungal meningitides and a variety of noninfectious processes.[44] Pressure may be falsely elevated when the patient is tense or obese or has marked muscle contraction.

Collection of Fluid

At least three sterile tubes each containing at least 1 to 1.5 mL of CSF are obtained and numbered in sequence. A fourth tube may be desirable should later studies, such as viral cultures or a Venereal Disease Research Laboratory (VDRL) test for syphilis, become necessary. The fluid is sent to the laboratory for immediate analysis of turbidity, xanthochromia, glucose, protein, cell count and differential, Gram's stain, bacterial culture, and antigen testing (Table 109-1). In certain cases an India ink stain, a bacteriologic stain for acid-fast bacilli, or a VDRL test should be obtained. When only a small amount of fluid can be obtained, the most important studies are the cell count with differential, Gram's stain, and bacterial cultures. Ideally, the cell count should be performed on both the first and third or fourth tubes to help differentiate true CSF pleocytosis from contamination of the specimen by a traumatic LP.

Turbidity

The CSF is assessed immediately for turbidity or cloudiness by the person performing the LP. Because normal CSF is completely clear and colorless and is indistinguishable from water, any degree of turbidity is pathologic. Leukocytosis is the most common cause

www.ketabpezeshki.com 66485457-66963820

Table 109-1 Analysis of Cerebrospinal Fluid

TEST	NORMAL VALUE	SIGNIFICANCE OF ABNORMALITY
Cell count	≤5 WBC/mm³ ≤1 PMN/mm³ ≤1 eosinophil/mm³	Increased WBC counts are seen in all types of meningitis and encephalitis; increased PMN count suggests bacterial pathogen
Gram's stain	No organism	Offending organism identified 80% of the time in bacterial meningitis, 60% if patient has been pretreated
Turbidity	Clear	Increased turbidity with leukocytosis, blood, or high concentration of microorganisms
Xanthochromia	None	Presence of RBCs in spinal fluid for 4 hr before lumbar puncture; occasionally caused by traumatic tap (if protein ≥150 mg/dL) or hypercarotenemia
CSF-to-serum glucose ratio	0.6 : 1	Depressed in pyogenic meningitis or hyperglycemia; lag time if glucose given intravenously
Protein	15-45 mg/dL	Elevated with acute bacterial or fungal meningitis; also elevated with vasculitis, syphilis, encephalitis, neoplasms, and demyelination syndromes
India ink stain	Negative	Positive in one third of cases of cryptococcal meningitis
Cryptococcal antigen	Negative	90% accuracy for cryptococcal disease
Lactic acid	≤35 mg/dL	Elevated in bacterial and tubercular meningitis
Bacterial antigen tests	Negative	≥95% specific for organism tested; up to 50% false-negative rate
Acid-fast stain	Negative	Positive in 80% of cases of tuberculous meningitis if ≥10 mL of fluid

CSF, cerebrospinal fluid; *PMN,* polymorphonuclear leukocyte; *RBC,* red blood cell; *WBC,* white blood cell.

of CSF turbidity; counts greater than 200 cells/mm³ usually cause clinically detectable changes in CSF clarity.[67]

Cell Count and Differential

Normal adult CSF contains no more than 5 leukocytes/mm³ with at most one granulocyte (polymorphonuclear [PMN] leukocyte)[46,67,68]; therefore, the presence of more than one PMN or a total cell count of more than 5 cells/mm³ should be considered evidence of CNS infection. In addition, the presence of any eosinophil in the CSF is abnormal, although basophils may occasionally be seen in the absence of disease.[67] Pretreatment with a few doses of antibiotics, although possibly diminishing the yield of Gram's staining and cultures, should not affect the CSF cell counts in meningitis.[14,69,70]

The cell counts in bacterial meningitis are usually markedly elevated, sometimes exceeding 10,000 cells/mm³, and demonstrate a dramatic granulocytic shift.[46] In general, counts exceed 500 cells/mm³, with a preponderance of PMN leukocytes. However, the initial CSF analysis exhibits lymphocytosis (lymphocyte count greater than 50%) in 6 to 13% of all cases of bacterial meningitis. When only the patients with bacterial meningitis with fewer than 1000 cells/mm³ are considered, 24 to 32% have a predominance of lymphocytes.[71,72] In addition, the same population of patients often has only a mild disturbance of CSF glucose and protein levels. In well-established viral meningitis and encephalitis, counts are usually less than 500 cells/mm³, with nearly 100% of the cells being mononuclear.[32] Early (48 hours) presentations may reveal significant PMN pleocytosis and hence be indistinguishable from presentations in early bacterial meningitis.[73]

Similarly, normal cell counts and differentials, although reassuring, do not absolutely exclude bacterial meningitis.[68] Any patient thought to have a clinical syndrome compatible with meningitis requires hospital admission with frequent reevaluation, repeated LP, and antimicrobial therapy. In some patients who have symptoms or signs of meningitis and have a normal initial CSF analysis, CSF pleocytosis may develop within 24 hours; the causative organism may be cultured from the original "normal" CSF.

Brain abscess and parameningeal infections, such as subdural empyema and epidural abscess, usually display CSF cell counts and differentials similar to those of viral meningitis and encephalitis, although the CSF may also be normal.

A traumatic LP is suggested by the presence of a clot in one of the tubes or the clearing of the CSF and a decreasing red blood cell (RBC) count from tubes one to three. In the presence of a traumatic LP, one may estimate the true degree of CSF white blood cell (WBC) pleocytosis with the following formula[67]:

$$\text{True CSF WBC} = (\text{measured CSF WBC}) \times \frac{(\text{CSF RBC}) \times (\text{blood WBC})}{\text{blood RBC}}$$

Alternatively, when peripheral cell counts are normal, the CSF from a traumatic LP should contain about 1 WBC per 700 RBCs.

Gram's Stain

A properly performed Gram's stain of a centrifuged specimen of CSF identifies the causative organism approximately 80% of the time in cases of bacterial meningitis.[70] Gram's stain characteristics of the most commonly encountered organisms are described in Table 109-2. The yield from this procedure is diminished by 20 to 30% when there has been prior treatment with antibiotics.[14]

Table 109-2 Gram's Stain Characteristics of Selected Meningeal Pathogens

PATHOGEN	TYPICAL CHARACTERISTICS
Staphylococci	Gram-positive cocci: singles, doubles, tetrads, clusters
Streptococcus pneumoniae	Gram-positive cocci: paired diplococci
Other streptococci	Gram-positive cocci: pairs and chains
Listeria monocytogenes	Gram-positive rods: single or chains
Neisseria meningitidis	Gram-negative cocci: negative paired diplococci; kidney or coffee bean appearance
Haemophilus influenzae	Gram-negative coccobacilli: "pleomorphic" bacilli
Enterobacteriaceae (including *Escherichia coli*)	Gram-negative rods
Pseudomonas aeruginosa	Gram-negative rods

www.ketabpezeshki.com 66485457-66963820

Misidentification of gram-positive organisms as gram negative is also known to occur more commonly among pretreated patients because organisms with damaged walls stain unpredictably.

Xanthochromia

Xanthochromia refers to the yellowish discoloration of the supernatant of a centrifuged CSF specimen. Xanthochromia is abnormal and results from the lysis of RBCs and release of the breakdown pigments oxyhemoglobin, bilirubin, and methemoglobin into the CSF. This process normally begins within 2 hours, and pigments may persist up to 30 days; therefore, early analysis of the LP specimen is essential. If a traumatic tap has introduced enough plasma to raise the CSF protein level to 150 mg/dL or more, blood pigments may cause xanthochromia. If the CSF protein level is less than 150 mg/dL, however, and systemic hypercarotenemia does not exist, xanthochromia of a centrifuged CSF specimen should suggest that subarachnoid hemorrhage has occurred.[67]

Glucose

When the serum glucose concentration is normal, the CSF glucose concentration is usually between 50 and 80 mg/dL. The CSF glucose concentration is normally in a ratio of 0.6 : 1 to the serum glucose concentration, except with marked systemic hyperglycemia, when the ratio is closer to 0.4 : 1. Therefore, a CSF-to-serum glucose ratio of less than 0.5 in normoglycemic subjects or 0.3 in hyperglycemic subjects is abnormal and may represent the impaired glucose transport mechanisms and increased CNS glucose use associated with pyogenic meningitis.[46,67] Mild decreases in the CSF glucose level may occur with certain viral and parameningeal processes. However, bacterial or fungal meningitis should be presumed to be the cause of low CSF glucose concentration, termed hypoglycorrhachia, until each is clearly excluded.[74] If the serum glucose level has increased rapidly (e.g., after intravenous administration of 50% dextrose in water), equilibration in the CSF may take up to 4 hours, and therefore the interpretation of CSF-to-serum glucose ratios may be unreliable.

Protein

The normal CSF protein level in adults ranges from 15 to 45 mg/dL. An elevated CSF protein level, usually higher than 150 mg/dL, commonly occurs with acute bacterial meningitis.[46] When a traumatic LP has occurred, the CSF protein level can be corrected for the presence of blood by subtracting 1 mg/dL of protein for each 1000 RBCs.[67] Elevated CSF protein concentrations can result from any cause of meningitis, subarachnoid hemorrhage, CNS vasculitis, syphilis, viral encephalitis, neoplasms, and demyelination syndromes.[67] A greatly elevated CSF protein level (>1000 mg/dL) in the presence of a relatively benign clinical presentation should suggest fungal disease.[13]

India Ink Preparation

India ink staining of the CSF should be performed when a diagnosis of cryptococcal meningitis is being considered. The demonstration of budding organisms (Fig. 109-3) is virtually diagnostic for cryptococcal disease but occurs in only one third of the cases.[13] A more definitive diagnostic test is the cryptococcal antigen, which appears to have a similar sensitivity when it is measured in serum, CSF, or urine.[75]

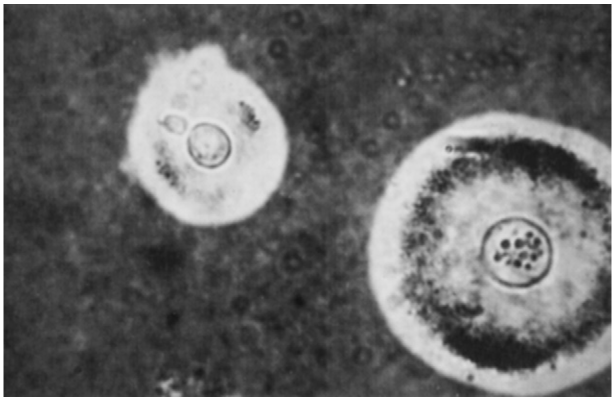

Figure 109-3. India ink staining of cerebrospinal fluid showing cryptococcal meningitis.

Lactic Acid

Although nonspecific, elevations in CSF lactic acid concentrations (>35 mg/dL) are potentially indicative of bacterial meningitis, and lactate may rise before the decline in glucose.[76,77] Normal lactate levels (<35 mg/dL) are usually seen in patients with viral meningitides. A systematic review suggested that with respect to efficacy, CSF lactate outperforms other commonly used laboratory findings (glucose, protein, leukocyte count).[78] The authors did observe that the CSF lactate level is less helpful if it is low but that higher values are highly associated with bacterial meningitis.

Antigen Detection

Counterimmunoelectrophoresis (CIE), latex agglutination, and coagglutination are methods of detecting specific antigens. These tests are particularly useful in patients receiving antibiotic treatment before CSF sampling because the tests depend on the presence of only an antigen and not viable organisms.

The CIE techniques that are performed for the most common bacterial pathogens demonstrate high sensitivity and specificity for bacterial antigens, particularly when they are performed on CSF, blood, and urine simultaneously. Latex agglutination techniques are, however, more rapid and sensitive and are replacing CIE in many facilities. Although reported results vary, the sensitivities of antigen tests are 50 to 90% for *Neisseria* organisms, 50 to 100% for *S. pneumoniae,* and approximately 80% for *H. influenzae.* A specific agglutination test for cryptococcal antigen is also highly sensitive (90%) and specific. Cultures are always indicated because a negative antigen test result does not exclude the possibility of any particular bacterial or fungal etiology.

Antigen and antibody testing is also being used to identify viral and atypical pathogens. These tests have particular utility in HSV encephalitis. Enzyme-linked immunosorbent assays can detect HSV antibody production.[79] Unfortunately, the appearance of antibody in CSF occurs too late to aid in any therapeutic decision analysis. PCR amplification and the identification of HSV DNA have demonstrated a sensitivity of 95 to 100% and a specificity of 100% early in the disease and have markedly decreased the need for diagnostic brain biopsy in this disorder.[80] PCR has improved the diagnosis of tuberculous meningitis, with a sensitivity of 80 to 85% and a specificity of 97 to 100%, and is superior to standard techniques.[81,82] PCR has additionally been shown to be superior in identifying bacteria, enteroviruses, and other viral etiologic agents in both immunocompromised and immunocompetent patients.[83,84] Reported sensitivities of detection in CSF by PCR for *N. meningitidis, H. influenzae,* and *S. pneumoniae* are 88%, 100%, and 92%, with nearly 100% specificity.[85,86] The sensitivities of bacteriologic culture are much lower, especially for *N. meningitidis* at 37 to 55% and *H. influenzae* at 50%.[87,88]

In addition, PCR assays have nearly tripled the yield of viral culture in identifying the etiologic agent.[89] In studies of enteroviral

www.ketabpezeshki.com 66485457-66963820

meningitis, sensitivities and specificities for PCR ranged from 86 to 100% and 92 to 100%, respectively.[90] PCR has been shown to be at least as sensitive as culture technique in detecting cryptococcal meningitis. Quantitative PCR may be of benefit in monitoring response to therapy in some forms of severe disease.[35]

The growing availability of these molecular techniques does not, however, suggest that they should be routinely used as initial diagnostic tests. Most cases of acute bacterial meningitis are readily diagnosed and treated on the basis of the standard Gram's stain and culture. PCR should be reserved for less clear presentations, patients pretreated with antibiotics, and cases in which concern exists for tuberculous, cryptococcal, and treatable viral CNS infections.[91] A reasonable approach is to save the CSF and to consider ordering PCR when acute infection is strongly suspected on the basis of the initial results from the cell count and Gram's stain.

Bacteriologic Cultures

Although results are not available for emergency management, bacteriologic cultures of CSF should be performed. Bacterial culture yields are significantly decreased in patients pretreated with antibiotics. Viral cultures may also be indicated.

Other Tests

A variety of additional, nonspecific tests of CSF have been advocated. These include measurement of CSF lactate dehydrogenase, C-reactive protein, and the limulus lysate test; however, none of these has demonstrated a high degree of clinical usefulness. Likewise, the evaluation of CSF chloride as a diagnostic aid for tuberculous meningitis is no longer clinically relevant.

Neuroimaging Techniques

Cranial CT or magnetic resonance imaging (MRI) is indicated in the evaluation of any patient with presumed CNS infection in whom there is the possibility of an intracranial abscess, intracranial hemorrhage, or mass lesion. In the diagnostic evaluation of acute meningitis, however, a CT scan should not unnecessarily delay LP or antimicrobial therapy. The CT scan may also show hypodense lesions in the temporal lobes in patients with HSV encephalitis, although MRI reveals this abnormality much earlier in the disease process. A contrast-enhanced cranial CT scan or MRI scan is invaluable in the diagnosis of a CNS abscess.[45] MRI is also helpful in the evaluation of other infectious and noninfectious encephalitides.

Additional Investigations

As with other infectious diseases, the complete blood count with differential is a nonspecific adjunct in the diagnostic evaluation of a patient thought to have a CNS infection. The peripheral cell counts are often normal in the presence of significant disease and may even be depressed, particularly in elders or immunosuppressed persons. A "normal" leukocyte count and differential should not dissuade one from performing a diagnostic LP, obtaining a CT scan, or otherwise pursuing the diagnosis of a CNS infection. Serum C-reactive protein is nonspecific, but a negative test result is potentially helpful.[92] Procalcitonin is emerging as a promising serum marker in infectious disease; however, there is not convincing evidence at this point to advocate its use to attempt to rule out bacterial meningitis.[93]

Even when antimicrobial therapy has already been administered, two or three blood culture specimens should be obtained for all patients who are being evaluated for a CNS infection. The blood cultures can improve the identification of the causative organisms, especially with pneumococcus and, to a lesser degree, meningococcus. Although blood cultures are not immediately useful in the initial diagnosis of meningitis, they may be of considerable clinical importance later in management of the disease. The cultures are helpful in identifying a causative organism in only a small minority of cases of brain abscess.

As many as 50% of patients with pneumococcal meningitis also have evidence of pneumonia on an initial chest radiographic study. This association occurs in less than 10% of the cases of meningitis caused by *H. influenzae* type b and *N. meningitidis* and in approximately 20% of cases of meningitis caused by other organisms. The identification of a pulmonary infection on chest radiography may assist in identification of causative organisms and appropriate antimicrobial therapy in approximately 10% of cases of brain abscess.[45]

Other ancillary investigations, such as echocardiography, cultures of other body fluids, and bone scans, may be undertaken as necessary to evaluate coexistent or complicated disease. Serum electrolyte, glucose, urea nitrogen, and creatinine levels should be measured to facilitate the interpretation of the CSF glucose level and to establish the level of renal function and the state of electrolyte balance. Although organism-specific abnormalities are uncommon, hyponatremia has been associated with tuberculous meningitis.

A number of characteristic but not pathognomonic electroencephalographic abnormalities have been associated with HSV type 1 encephalitis. Focal or lateralized electroencephalographic abnormalities in the presence of an encephalitis syndrome should be considered strong evidence supporting a diagnosis of HSV encephalitis.[94]

DIFFERENTIAL CONSIDERATIONS

Patients with meningitis may have symptoms and signs ranging from mild headache with fever to frank coma and shock. To facilitate the discussion of diagnosis and treatment, meningitis may be divided into three clinical syndromes: acute meningitis, subacute meningitis, and chronic meningitis.

Acute meningitis encompasses patients with obvious signs and symptoms of meningitis who are evaluated in less than 24 hours after the onset of their symptoms and who rapidly deteriorate. In many of these patients the diagnosis of meningitis is not in doubt, and the crucial step is to initiate antimicrobial therapy immediately. The most likely pathogens in this syndrome are *S. pneumoniae* and *N. meningitidis*. Although *H. influenzae* has been reported in this context, it is not commonly implicated in the adult population.[16,69]

In the syndrome of subacute meningitis, the symptoms and signs causing the patient to seek care have developed during a period of 1 to 7 days. This syndrome includes virtually all cases of viral meningitis along with most of the bacterial and some of the fungal causes.[14,15] The differential diagnosis depends on the symptoms and signs at presentation. Among elders and immunosuppressed individuals, a change in the patient's mental status may be the only presenting sign in meningitis. Even when a fever is present, the patient's change in mental status may be misattributed to another disease outside the CNS, such as pneumonia or urinary tract infection; neck stiffness may be misattributed to degenerative joint disease. Elders are at high risk for meningitis, and rather than constituting a diagnostic endpoint, the identification of an infection outside the CNS in elders is a clear indication for LP because of the risk of bacteremic seeding by the involved organisms.

The differential diagnosis of encephalitis and brain abscess occurs in the context of the subacute meningitis syndrome. Brain abscess should be considered, especially if fever is minimal or absent or if there are focal neurologic findings. The presence of

www.ketabpezeshki.com 66485457-66963820

fever, altered sensorium, headache, seizures, and personality change is consistent with encephalitis. In addition, diagnoses such as subdural empyema, brain tumor, subarachnoid hemorrhage, subdural hematoma, and traumatic intracranial hemorrhage should be considered. In these circumstances, a cranial CT scan should be obtained before LP is performed.

The spectrum of chronic meningitis includes some of the viral meningitides as well as meningitis caused by tubercle bacilli, syphilis, and fungi. Many of the patients in this group have had symptoms for at least 1 week before presentation and generally have a prolonged indolent course marked by difficult and changing diagnoses and multiple therapies.[12,13] Prediction rules have been both derived and validated and have not yet diffused into widespread practice, probably because of limitations in the models, shifts in the epidemiology of the causative organisms, and relatively small sample sizes.[95]

MANAGEMENT

Assessment and Stabilization

Septic shock, hypoxemia, seizures, cerebral edema, and hypotension resulting from dehydration require aggressive management. When possible, a thorough history should be obtained from the patient, family members, or ambulance personnel with particular emphasis on preexisting conditions that may complicate the patient's disease. Examples include recent neurosurgery, trauma, history of leukopenia, immune suppression, and diabetes mellitus.

Hypotension or shock is treated with isotonic crystalloid infusion, high-flow oxygen, and pressors. Intravenous administration of dextrose may be required for hypoglycemia secondary to depletion of glycogen stores. Alcoholic or nutritionally compromised patients should also receive 50 to 100 mg of thiamine intravenously (IV). In cases of moderate to severe hypotension, central venous pressure monitoring should be initiated on the basis of sepsis guidelines and used to determine additional intravenous fluids or vasopressors. Concern has been raised about brain edema with large amounts of crystalloid fluid in patients with meningitis. However, in children, once fluid volume and vital signs are normalized through resuscitation, there does not appear to be evidence to restrict fluids, and appropriate maintenance fluids should be instituted.[96]

Active airway management with endotracheal intubation may be required in severely ill patients with meningitis, particularly in cases of coma, recurrent seizures, or severe accompanying pulmonary infection. Cardiac monitoring may also be necessary, particularly in elderly patients, those with known coronary disease, and those with an altered mental status. Seizures are a particularly prominent component of the clinical presentation in patients with a brain abscess but may also occur with any CNS infection, especially when an underlying seizure disorder is present.

If acute cerebral edema or an elevated intracranial pressure is present, it is managed by immediate intubation and adequate ventilation. Osmotic agents such as mannitol or diuretics such as furosemide may be used, but caution should be exercised if shock or uncontrolled hypotension is present. If diuretics or osmotic agents are administered, one must ensure that the patient does not become volume depleted and hypotensive.

Definitive Therapy

Bacterial Meningitis

Therapy for bacterial meningitis requires antibiotics that penetrate the blood-brain barrier and achieve adequate CSF concentrations, are bactericidal against the offending organism in vivo, and maintain adequate tissue levels to treat the infection effectively.

Until the pathogenetic organism is identified, broad-spectrum coverage of the most common pathogens is necessary (Table 109-3). Many authorities recommend cefotaxime or ceftriaxone, plus vancomycin to cover potentially resistant organisms.[97] High-dose ampicillin is also added if concern exists about *Listeria*.[97] In patients allergic to penicillin and cephalosporins, meropenem or chloramphenicol plus vancomycin may be effective while the outcome of desensitization techniques is awaited.[97]

After the pathogen is identified, more targeted therapy can be instituted. It is prudent to refer to a current antimicrobial

Table 109-3 Recommendations for Empirical Antimicrobial Therapy for Purulent Meningitis Based on Patient Age and Specific Predisposing Condition

PREDISPOSING FACTOR	COMMON BACTERIAL PATHOGENS	ANTIMICROBIAL THERAPY
Age		
<1 month	*Streptococcus agalactiae, Escherichia coli, Listeria monocytogenes, Klebsiella* species	Ampicillin plus cefotaxime or ampicillin plus an aminoglycoside
1-23 months	*Streptococcus pneumoniae, Neisseria meningitidis, S. agalactiae, Haemophilus influenzae, E. coli*	Vancomycin plus a third-generation cephalosporin*,†
2-50 years	*N. meningitidis, S. pneumoniae*	Vancomycin plus a third-generation cephalosporin*,†
>50 years	*S. pneumoniae, N. meningitidis, L. monocytogenes,* aerobic gram-negative bacilli	Vancomycin plus ampicillin plus a third-generation cephalosporin*,†
Head trauma		
Basilar skull fracture	*S. pneumoniae, H. influenzae,* group A β-hemolytic streptococci	Vancomycin plus a third-generation cephalosporin*,†
Penetrating trauma	*Staphylococcus aureus,* coagulase-negative staphylococci (especially *Staphylococcus epidermidis*), aerobic gram-negative bacilli (including *Pseudomonas aeruginosa*)	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem
Postneurosurgery	Aerobic gram-negative bacilli (including *P. aeruginosa*), *S. aureus,* coagulase-negative staphylococci (especially *S. epidermidis*)	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem
CSF shunt	Coagulase-negative staphylococci (especially *S. epidermidis*), *S. aureus,* aerobic gram-negative bacilli (including *P. aeruginosa*), *Propionibacterium acnes*	Vancomycin plus cefepime,‡ vancomycin plus ceftazidime,‡ or vancomycin plus meropenem‡

From Tunkel AR, et al: Practice guidelines for bacterial meningitis. Clin Infect Dis 39:1267-1284, 2004.
* Ceftriaxone or cefotaxime.
† Some experts would add rifampin if dexamethasone is also given.
‡ In infants and children, vancomycin alone is reasonable unless Gram stains reveal the presence of gram-negative bacilli.

www.ketabpezeshki.com 66485457-66963820

reference to guide therapy in all instances, given rapid changes in etiologic spectrum, drug resistance, and available agents. Duration of treatment varies, and in certain situations (namely, epidemics in sub-Saharan African), long-acting chloramphenicol or ceftriaxone is effective.[98]

Corticosteroid treatment is additionally recommended in adult acute bacterial meningitis, although the evidence of efficacy is becoming less compelling over time. Animal studies demonstrate the salutary effects of the administration of corticosteroids in experimental pneumococcal meningitis, including reduced brain edema, CSF pressure, and CSF lactate levels.[99] Earlier resolution of the clinical and CSF stigmata of meningitis and a decrease in long-term hearing loss are observed in infants and children given dexamethasone with cefuroxime or ceftriaxone compared with those receiving the antibiotic alone, particularly when *H. influenzae* is the offending agent.[100] In adult bacterial meningitis, an absolute risk reduction of 10% for unfavorable outcome is seen when dexamethasone is given either 15 minutes before or concomitantly with antibiotics and continued for 4 days at 6-hour intervals.[101] This benefit is greatest in those with *S. pneumoniae*. Subgroup analyses for different causative organisms did not establish a benefit; however, the study was not designed with adequate power to detect improved outcomes. In addition, amoxicillin and penicillin were the most commonly used initial therapy at the time of that study because of the process of health care delivery in Europe, in which nearly all patients were seen initially in an office-based practice. A randomized controlled trial did not demonstrate a benefit of adjuvant dexamethasone in adult patients, even when only those with *S. pneumoniae* were included in a secondary analysis.[102] In the current era of initial empirical parenteral therapy, rising β-lactam resistance, the possibility of the decreased CSF penetration of vancomycin after dexamethasone treatment, and shifts in the likely causative organisms secondary to vaccination campaigns, the true effectiveness of dexamethasone is unclear. The most recent meta-analysis suggests a benefit for patients in the developed (but not developing) world, but the included studies suffer from one or more of the aforementioned limitations.[103] A pooled analysis of patient-level data was less conclusive, suggesting that the benefit of adjunctive dexamethasone for any "subgroup of patients with bacterial meningitis remains unproven."[104] Despite uncertainty from conflicting trials, an initial dose of dexamethasone 10 mg IV is recommended before or concurrent with empirical antibiotics in patients with suspected community-acquired meningitis and without signs of septic shock. Given the potential adverse effects of high-dose corticosteroids in patients with septic shock, the use of low-dose hydrocortisone at 50 mg IV instead of high-dose dexamethasone is a reasonable approach, although it has not been proved in randomized controlled trials of patients with both septic shock and meningitis.[105,106]

In pediatric meningitis, the evidence that adjunctive dexamethasone is helpful is less compelling. Invasive *H. influenzae* type b and pneumococcal infections have drastically been reduced by vaccination.[19] A randomized trial of dexamethasone in childhood meningitis in sub-Saharan Africa did not demonstrate a benefit.[107] A retrospective analysis from U.S. administrative data did not demonstrate any mortality benefit to adjunctive dexamethasone.[108] Current recommendations are organism specific, which presents a major limitation as recommendations are to begin empirical therapy before laboratory results in suspicious cases. For *H. influenzae* type b (Hib): "dexamethasone may be beneficial for treatment of infants and children with Hib meningitis to diminish the risk of neurological sequelae, including hearing loss, if given before or concurrently with the first dose of antimicrobial agent(s). There probably is no benefit if dexamethasone is given more than 1 hour after antimicrobial agent(s)."[109] For *S. pneumoniae:* "for infants and children 6 weeks of age and older, adjunctive therapy with dexamethasone may be considered after weighing the potential benefits and possible risks. Experts do not agree on a recommendation to use corticosteroids in pneumococcal meningitis; data are not sufficient to demonstrate a clear benefit in children. If used, dexamethasone should be given before or concurrently with the first dose of the antimicrobial agent."[110] The implication for frontline physicians caring for children is that unless the causative organism is known before antibiotic treatment, there is probably little role for adjunctive dexamethasone in children.

Viral Meningitis

No specific agents are available to treat most types of viral meningitis. Investigational agents in development may reduce symptoms in enterovirus meningitis[111]; however, with the exception of HSV meningitis, the viral meningitides contracted in the United States are generally characterized by a short, benign, self-limited course followed by a complete recovery. The primary therapeutic consideration in cases of viral meningitis is therefore the validity of the diagnosis. Early cases of viral meningitis may be indistinguishable from bacterial meningitis, and this confusion may not be resolved by CSF analysis; therefore, when any doubt exists about the veracity of the diagnosis, appropriate culture specimens should be obtained and the patient admitted to the hospital. Antimicrobial therapy for presumed bacterial meningitis may be initiated on the basis of the clinical presentation or may be withheld pending the outcome of close clinical observation and repeated LP in 8 to 12 hours.

Viral Encephalitis

Specific therapy for meningoencephalitis from HHV is available. Acyclovir remains the current choice and is capable of substantially improving the patient's outcome. When the diagnosis of herpes meningoencephalitis is suspected or established, acyclovir should be administered in a dose of 10 mg/kg IV every 8 hours.[81] Ganciclovir, foscarnet, and cidofovir are also effective in HHV infections, and pleconaril has been effective in enteroviral disease. Additional antiviral treatments are in development.[34,35,111]

Tuberculous Meningitis

Early chemotherapeutic intervention in acute tuberculous meningitis improves the patient's prognosis. A strong clinical suggestion of this disease is an adequate indication to begin antituberculous therapy. A standard treatment regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin.[97] Corticosteroids have also been shown to decrease secondary complications.[97]

Fungal Meningitis

The treatment of fungal meningitis is complex.[13] Four agents are commonly used: amphotericin B, flucytosine, miconazole, and fluconazole. Of these, amphotericin B, either alone or in combination with flucytosine, is the most commonly recommended initial therapeutic regimen.[97] These diseases are rarely acutely life-threatening but rather are slowly progressive. Prolonged therapy, often with multiple agents, is necessary. The initiation of antifungal therapy is rarely indicated in the emergency department.

Central Nervous System Abscess

The treatment of cerebral abscess is complex, and neurosurgical consultation is indicated. The location, size, and number of abscesses influence the choice of medical management, surgical excision, aspiration, or a combination of these modalities.[38] In

www.ketabpezeshki.com 66485457-66963820

general, small multiple abscesses are more appropriately treated medically, whereas large, surgically accessible lesions should be excised. Empirical antimicrobial therapy before identification of specific organisms by aspiration or surgical excision should be guided by the principles of CSF penetration and the coverage of likely pathogens.

Otogenic and sinogenic abscesses are often treated with cefotaxime or ceftriaxone plus metronidazole.[97] Abscesses with traumatic or neurosurgical causes should have antimicrobial coverage for *S. aureus* or methicillin-resistant *S. aureus*. Patients at high risk for tuberculous, fungal, or parasitic abscess should also receive coverage for the suspected etiologic agent. Corticosteroids should be reserved specifically for management of any attendant cerebral edema; in other circumstances, steroid use is associated with increased mortality. In cases in which the etiology is bacterial endocarditis, valve replacement is often required.[112]

Chemoprophylaxis

Among household contacts, the incidence of transmission of meningococcus is approximately 5%; therefore, it is recommended that household contacts of bacteriologically confirmed cases receive rifampin (adults, 600 mg; children older than 1 month, 10 mg/kg; children younger than 1 month, 5 mg/kg) orally every 12 hours for a total of four doses.[97] In addition, these contacts should be advised to watch for fever, sore throat, rash, or any symptoms of meningitis. They should be hospitalized with appropriate intravenous antimicrobial therapy if there are signs that active meningococcal disease is developing because rifampin is ineffective against invasive meningococcal disease. Intimate, nonhousehold contacts who have had mucosal exposure to the patient's oral secretions should also receive rifampin prophylaxis. Health care workers are not at increased risk for the disease and do not require prophylaxis unless they have had direct mucosal contact with the patient's secretions, as might occur during mouth-to-mouth resuscitation, endotracheal intubation, or nasotracheal suctioning. Ciprofloxacin 500 mg by mouth (adults only) and ceftriaxone 250 mg intramuscularly (125 mg intramuscularly for children younger than 15 years) provide single-dose alternatives.[97]

There is no indication for chemoprophylaxis in pneumococcal meningitis. Rifampin prophylaxis for the contacts of patients with *H. influenzae* type b meningitis is recommended for nonpregnant household contacts when there are children younger than 4 years in the household[97] (adults, 600 mg by mouth; children, 20 mg/kg by mouth daily for 4 days).

Immunoprophylaxis

A quadrivalent vaccine based on the polysaccharide capsule and conferring protection against group A, C, Y, and W-135 meningococci has been in routine use by the U.S. military since the 1980s.[113] However, the capsular polysaccharide vaccines used to immunize adults are neither immunogenic nor protective in children younger than 2 years because of poor antibody response. In addition, no licensed vaccine is currently available against the serogroup B meningococcus.[47] The serogroup B capsular polysaccharide has proved to be poorly immunogenic in both adults and children.[114] The sequence variation of the surface proteins and cross-reactivity of the group B polysaccharide with human tissues have further impeded efforts to develop a successful vaccine. Efforts to enhance the immunogenicity and protective efficacy of meningococcal vaccines have focused on use of conjugate methods that link polysaccharides and carrier proteins. Serogroup C and serogroup C + Y conjugate vaccines have been developed and used effectively.[115] Current recommendations for the quadrivalent vaccine are evolving. The vaccine is recommended in established meningococcal epidemics and for travelers to countries where meningococcal disease is currently epidemic. Elective vaccination of college freshmen has been recommended by the Advisory Committee on Immunization Practices (ACIP) in the United States and public health authorities in the United Kingdom.[116,117] The United Kingdom has also implemented universal childhood immunization with a group C conjugate vaccine.[115]

The development of effective pneumococcal vaccines has been hampered by the large number of serotypes of the organism. A small number of serotypes, however, are responsible for most clinical pneumococcal disease, and a 23-valent vaccine effective against many of these principal serotypes has been developed.[118] The recommendations for this polyvalent pneumococcal vaccine are targeted primarily at prevention of pneumonia, despite a potential beneficial effect for meningitis. A single dose of the vaccine should be considered for elderly or debilitated patients, especially those with pulmonary disease, and for patients with impaired splenic function, splenectomy, or sickle cell anemia.[18] A heptavalent conjugated pneumococcal vaccine has also been developed and is recommended for universal childhood immunization by the ACIP.[119]

A conjugate vaccine effective against *H. influenzae* type b has been developed for use in the pediatric but not the adult population. It appears to be approximately 90% protective and has a very low incidence of adverse reactions.[120] Modern childhood immunization against *H. influenzae* type b has raised the average age of patients afflicted with *Haemophilus* meningitis to 25 years and decreased the incidence of meningitis of any etiology by 55%.[91]

Vaccination is also available to confer immune protection against Japanese encephalitis virus, and it is recommended for people performing extensive outdoor activities or spending more than 30 days in endemic areas during transmission seasons.[121] The reported protective efficacy of the vaccine is approximately 90%. Although there is no current human vaccine for WNV, vaccines for nonhuman mammals have been developed.[34]

DISPOSITION

With the exception of viral meningitis, all but the most chronic CNS infections require initial inpatient evaluation and treatment. Bed rest, analgesics, and the institution of appropriate intravenous antimicrobials are indicated.

Some patients with suspected viral meningitides merit hospitalization. These include patients with more severe disease, immunocompromise, suspicion of HSV meningitis, and potential nonviral causes. Some authorities manage patients with classic presentations of viral meningitis as outpatients and ensure close follow-up within 24 hours. Others admit all patients until the more serious causes, such as early bacterial meningitis and encephalitis, can be excluded with certainty.

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- CNS infection should be considered in all patients with headache, neck stiffness, fever, altered sensorium, or diffuse or focal neurologic findings.
- Lumbar puncture with sampling of CSF is the only reliable method of assessing the presence or absence of meningitis. In the absence of contraindications, any suspicion of meningitis mandates performance of lumbar puncture.
- Early initiation of antimicrobial therapy is mandatory in any case of suspected acute CNS infection. Antibiotic administration must not be delayed for CSF analysis or performance of neuroimaging studies.
- Antibiotic chemoprophylaxis should be ensured for close contacts of patients with meningitis resulting from *Neisseria meningitidis* or *Haemophilus influenzae*. Single-dose and multiple-dose regimens are available.
- Vaccination against *N. meningitidis* is recommended for certain at-risk populations but does not afford protection against serogroup B infection.
- Concomitant CNS infection should be strongly considered in any patient with another severe systemic infection, such as urinary tract infection or pneumonia.

Section Eight
PSYCHIATRIC AND BEHAVIORAL DISORDERS

CHAPTER 110
Thought Disorders

Robert S. Hockberger and John R. Richards

PERSPECTIVE

In the 1800s, Morel introduced the term *dementia praecox* to describe a progressive deterioration of mental functioning and behavior with onset in adolescence to early adult life.[1] In 1911, Bleuler detailed the specifics of this disorder, which he termed *schizophrenia,* or "split-mindedness."[2] Early treatments of schizophrenia included ice water immersion, barbiturates or insulin to induce prolonged narcosis or coma, seizure induction with pentylenetetrazol, electroconvulsive therapy, and frontal leukotomy.[3] The effectiveness of these treatments was marginal at best, and until recent times, most schizophrenic patients were relegated to lifelong institutionalization.

Modern-era pharmacotherapy for schizophrenia, with chlorpromazine and haloperidol, began in the early 1950s. This treatment proved so successful that by the 1960s, most psychiatrists believed that schizophrenia could be successfully managed in the outpatient setting. In 1965, the Community Mental Health Centers Act initiated the release of medicated schizophrenic patients into the community.[4] Unfortunately, inadequate family support, unavailability of jobs and low-cost housing, and lack of funding for social services and outpatient psychiatric care left many of these individuals isolated without the tools needed for resocialization. Currently 20 to 40% of homeless people in the United States have a major mental illness.[5] Emergency departments frequently serve as the primary entry point into the mental health care system for many of these individuals.[6]

PRINCIPLES OF DISEASE

The etiology of schizophrenia is currently believed to be heterogeneous from interaction of biologic and environmental factors. Studies involving adopted twins whose biologic parents have schizophrenia demonstrate a strong genetic basis for the disorder. Although the overall incidence of schizophrenia in the general population is roughly 1%, it is approximately 10% in first-degree biologic relatives of individuals with the disorder.[7] With regard to the pathophysiologic mechanism of schizophrenia, dopaminergic, serotonergic, cholinergic, and glutamatergic systems have been implicated.[8-11]

Schizophrenia is also postulated to be a neurodevelopmental disorder resulting from the influence of environmental factors on genetically predisposed individuals. Disruptions in fetal brain development, caused by perinatal hypoxia, poor nutrition, infection, and other insults, may set the stage for subsequent development of schizophrenia.[1,12] New imaging techniques have documented structural brain abnormalities, most of which appear to be developmental rather than degenerative in nature.[8] Evidence supports the existence of a progressive continuum of psychotic illness, beginning with unipolar depression and progressing to bipolar illness, schizoaffective psychoses, and finally schizophrenia.[1,13,14]

CLINICAL FEATURES

Overt signs of schizophrenia usually become manifested during adolescence or early adult life. Many patients describe a childhood with few interpersonal relationships and a withdrawn, eccentric personality.

Phases of Schizophrenia

The development of schizophrenia involves three phases.[15] The *premorbid phase* is characterized by the development of "negative" symptoms with deterioration in personal, social, and intellectual functioning. Patients progressively withdraw from social interactions and neglect personal appearance and hygiene, which negatively affects their work, school, and home life.

The *active phase* is usually precipitated by a stressful event with development of "positive" symptoms, such as active delusions, hallucinations, and bizarre behavior. Patients may become agitated or exhibit a hypervigilant withdrawal state characterized by rocking or staring. It is during this phase that they are most likely to be brought to the emergency department by family, friends, coworkers, or the police.

In the *residual phase,* patients are left with impaired social and cognitive ability, marked by bizarre ideation, delusions, peculiar behavior, poor personal hygiene, and social isolation. Most schizophrenic patients require a sheltered environment to function adequately. Despite a wide spectrum of severity, the general course for most patients is one of gradual deterioration with periodic episodes of psychotic decompensation.

Criteria for Schizophrenia

The diagnostic criteria for schizophrenia (Box 110-1) are outlined in the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, text revision (DSM-IV-TR).[15]

- The patient must exhibit two or more of the following symptoms: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms (such as flattening of affect, poverty of speech, or inability to perform goal-directed activities).
- There must be a sharp deterioration from the patient's prior level of functioning (work, school, self-care, or interpersonal relations), and there must be continuous signs of disturbance for at least 6 months.

www.ketabpezeshki.com 66485457-66963820

Box 110-1 Summary of DSM-IV-TR Criteria for Schizophrenia

A. Presence of two (or more) characteristic symptoms for 1 month (or more) unless treated
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms: affect flattening, alogia (poverty of speech), avolition (unable to perform goal-directed activities)

   Note: Only one symptom above is required if delusions are bizarre or hallucinations consist of a running commentary.

B. Sharp deterioration from prior level of functioning (i.e., work, self-care, interpersonal relations)

C. Continuous signs of disturbance for 6 months (or more)

D. Schizoaffective disorder and mood disorder with psychotic features have been ruled out

E. Not caused by substance abuse, medication, or a general medical condition

Modified from Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

- The diagnoses of schizoaffective and mood disorders with psychotic features must be excluded.
- In evaluating these patients, emergency physicians must exclude myriad medical conditions that can mimic or cause psychotic symptoms.

Delusions

The DSM-IV-TR defines *delusions* as "erroneous beliefs that usually involve a misinterpretation of perceptions or experiences."[15] The delusions seen with schizophrenia are most often persecutory, religious, or somatic.

Hallucinations

A *hallucination* is a sensory experience that exists only in the mind of the person experiencing it. Hallucinations associated with schizophrenia may be auditory, visual, olfactory, gustatory, or tactile. Auditory hallucinations (hearing voices) that are pejorative or threatening are especially common.

Disorganized Speech

Patients with schizophrenia experience loosening of associations, with thoughts shifting randomly from one topic to another without a logical connection. Their speech often shows lack of content. *Neologisms* (nonsense words invented by the patient) and *perseverations* (frequently repeated words or phrases) are common. On occasion, the patient's speech may be so severely disorganized that it is totally incoherent, termed *word salad*.

Grossly Disorganized or Catatonic Behavior

Schizophrenic patients have difficulty in formulating and producing goal-directed behavior. They are often found wandering about, disheveled, malnourished, talking to themselves, and exhibiting unpredictable agitation. It is this behavior that usually prompts family members, friends, or the police to bring them to the emergency department. Patients exhibiting catatonia appear to be completely unaware of their environment, maintain a rigid posture, and resist efforts to be moved.

Negative Symptoms

Three negative symptoms—flattening of affect, alogia, and avolition—account for a significant degree of the morbidity associated with schizophrenia. Patients with a *flattened affect* exhibit little facial expressiveness, eye contact, or body language. *Alogia*, or poverty of speech, is manifested by brief, laconic, empty replies to questioning. *Avolition* is characterized by an inability to initiate and to persist in goal-directed activities. Caution should be used in evoking negative symptoms to support a diagnosis of schizophrenia because similar symptoms may be found in patients with severe depression, chronic environmental understimulation, and treatment with neuroleptic medications.

DIAGNOSTIC STRATEGIES

Patients with Known Psychiatric Disorders

Patients with previously diagnosed thought disorders who present with mild to moderate exacerbation of their symptoms do not require extensive laboratory evaluation.[16] Because some of these patients may have coexisting substance abuse or undiagnosed medical disorders, a thorough history, detailed physical examination, and routine toxicology studies are indicated for most patients.[17-19] Patients exhibiting severe exacerbation of symptoms accompanied by marked agitation, violent behavior, or significantly abnormal vital signs should undergo more extensive evaluation.

Patients without Known Psychiatric Disorders

Many toxicologic and medical disorders can mimic schizophrenia. Patients with the apparent new onset of psychosis should receive a medical evaluation to exclude toxicologic and medical disorders.[20-23] Both the DSM-IV-TR and review articles on this topic emphasize that most toxicologic and medical causes of altered mental status that simulate acute schizophrenia are best recognized by patterns of presentation combined with focused testing based on one's index of suspicion for nonpsychiatric disease, rather than the reliance on a broad use of screening tests.

DIFFERENTIAL CONSIDERATIONS

Medical Disorders

Certain medications and medical disorders may affect thought processes, causing patients to exhibit abnormal behavior (Boxes 110-2 and 110-3). This behavior may range from mild personality changes to apparent acute psychosis, even in the absence of an underlying psychiatric disorder.[1] Factors that should alert one to a medical disorder include the following: history of substance abuse or a medical disorder requiring medication; patient's age older than 35 years without previous evidence of psychiatric disease; recent fluctuation in behavioral symptoms; hallucinations that are primarily visual in nature; presence of lethargy; abnormal vital signs; and poor performance on cognitive function testing, particularly orientation to time, place, and person. These and other factors may be helpful in differentiating functional (psychiatric) from organic (medical) causes of abnormal behavior and can be easily recalled with the mnemonic MADFOCS (Table 110-1).[24]

Although the classic textbook differentiation between functional and organic causes of abnormal behavior is straightforward, the evaluation of individual patients may be difficult.[21] A patient with underlying psychiatric disease may develop a medical disorder, which may worsen the patient's behavioral symptoms and

further cloud the distinction between functional and organic disease. This evaluation is particularly difficult in the emergency department when previous medical or psychiatric history is not available, the patient is uncooperative, and the time frame to make a disposition is brief. When the clinical differentiation between functional and organic disease is unclear on the basis of available information, a patient should be thoroughly evaluated to exclude a toxicologic or medical disorder.

Psychiatric Disorders

A previously undiagnosed patient who presents with an acute functional psychosis may ultimately be given one of several psychiatric diagnoses.[15] A *brief psychotic disorder* involves the sudden onset of psychotic symptoms in response to major stress and lasts several days to 1 month. Patients with *schizophreniform disorder* have similar symptoms that last longer than 1 month but less than 6 months. Whereas one third of individuals initially given the diagnosis of schizophreniform disorder recover within 6 months, the other two thirds retain their symptoms and are diagnosed as having schizophrenia. Patients with mood disorders may develop psychotic symptoms. If these symptoms are present only during periods of mood disturbance, the diagnosis of *mood disorder with psychotic features* is applied; if they persist longer than 2 weeks in the absence of prominent mood symptoms, the diagnosis of *schizoaffective disorder* is made. Patients with *personality disorders* may occasionally develop brief psychotic episodes under stress.

Ganser's syndrome is a symptom complex considered to be emotional in origin in which the patient may appear to have amnesia, hallucinations, or alterations in consciousness, usually in association with physical complaints. An individual with Ganser's syndrome may have psychotic symptoms for no apparent gain except to assume the role of the psychiatric patient.

Persons with a *delusional disorder* experience nonbizarre delusions that may dominate their lives. They may believe that famous people are in love with them (erotomanic type), that they have extraordinary powers with a special relationship to a deity or a famous person (grandiose type), that their sexual partner is unfaithful (jealous type), that they are being malevolently treated in some way (persecutory type), or that they have some physical defect or general medical condition (somatic type). Although patients with somatic delusions may experience tactile or olfactory hallucinations related to the delusional theme (e.g., the sensation of being infested with insects), the other features associated with schizophrenia are not present.

MANAGEMENT

General Approach

Patients with thought disorders may be agitated and hyperactive, may be withdrawn but hypervigilant, or may complain of somatic delusions. In addition, they may have paranoid ideation, may be angry they have been brought to the emergency department against their will, or may be frightened because they have been confronted by the police, restrained, and isolated. These patients may be disconcerting to staff because they are often irrational, erratic, and unpredictable in their behavior. Although emergency personnel should remain calm, empathetic, and reassuring in their interactions with patients exhibiting a thought disorder, they must also take steps to ensure staff safety whenever dealing with patients at risk for sudden violence. Such patients include those who have behaved violently before coming to the emergency department, those who physically or verbally threaten staff, and those who have an escalating level of agitation despite verbal attempts to calm them.

Each patient should have a thorough history and physical examination, including a detailed mental status evaluation, to rule out an organic brain syndrome. Valuable information can be obtained from family members, friends, coworkers, neighbors, prehospital personnel, police, and previous medical records (see Table 110-1).[24]

The most important step in evaluating a patient with a suspected thought disorder is the assessment of the patient's thought processes through the initial interview. The goals are to establish a positive physician-patient relationship, to make a correct diagnosis, and to gather enough information for an optimal disposition. The interview should be conducted in a quiet, comfortable room with adequate privacy. The examiner should be sitting, and if possible the interview should proceed to completion without interruption. If the patient is believed to be potentially dangerous but is not in need of immediate restraint, the interview should take place in an open area with security personnel nearby.

The emergency physician should begin with an introduction and should express the desire to be "of help" to the patient. The interview begins with open-ended questions designed to assess the patient's complaint and understanding of the current circumstances. Good opening questions include the following:

Do you understand why you have been brought here today?
You seem to be upset. Can you tell me why?
Do you have any idea why you might be having these symptoms?

The patient's appearance, body language, affect, and speech are observed during the responses to these questions.

A brief mental status examination is then performed. It may be initiated in a nonthreatening manner by stating, "I am now going to ask you a few questions to see how well you are concentrating." The patient is first asked about orientation to time, place, and person as this is the most sensitive test for differentiation of organic from functional disease. Patients who are disoriented require a detailed medical evaluation to exclude the presence of an organic brain syndrome. Patients who are oriented are assessed for attention, memory, intellectual functioning, and judgment in an attempt to determine their specific diagnosis, their potential for danger to themselves or others, and their degree of dysfunction and ability to care for themselves in the outpatient setting.

Rapid Tranquilization

When psychotic patients exhibit behavior that is violent or so disorganized and uncooperative that clinical evaluation is impossible, the temporary use of physical restraints is indicated while rapid tranquilization is initiated (see Chapter 189). The technique of rapid tranquilization involves serial doses of a high-potency antipsychotic agent until target symptoms, such as agitation and excessive psychomotor activity, are improved. The goal is to facilitate cooperation of the patient without causing unnecessary sedation, which inhibits further medical and psychiatric assessment. Oral, intramuscular, or intravenous doses can be given every 30 to 60 minutes until the patient becomes calm and more cooperative. If the patient is willing, an oral concentrate is preferred as it implies consent and takes effect almost as quickly as with intramuscular administration.

Haloperidol (Haldol), a butyrophenone, is widely used for rapid tranquilization in the United States.[25-27] The initial dose is 5 to 10 mg intramuscularly or intravenously for young to middle-aged patients and 0.5 to 2.0 mg intramuscularly or intravenously for elderly patients. Although rapid tranquilization with haloperidol quickly reduces tension, anxiety, and hyperactivity, delusions and hallucinations may not resolve for several weeks. In 2007 the U.S. Food and Drug Administration (FDA) released a non–black box warning about sudden death with the use of haloperidol in large doses or through the intravenous route. Droperidol (Inapsine), another butyrophenone, has also been extensively used for this indication in doses of 2.5 to 5.0 mg intramuscularly or intravenously.[28,29] Compared with haloperidol, droperidol has a faster onset and shorter duration of action and causes slightly more sedation. In 2001 the FDA issued a black box warning because of reports of a potential association between droperidol and prolonged QT interval, torsades de pointes, and sudden death.[30] Despite subsequent studies supporting both the efficacy and safety of droperidol, the FDA warning has resulted in a significant decrease of its use in clinical practice.[31,32] Neuroleptics should not be used for pregnant or lactating women, phencyclidine overdose, or anticholinergic drug–induced psychosis. In addition, although they may be useful to manage agitation in drug or alcohol intoxication, they should not be used as the sole agent in patients with drug or alcohol withdrawal. Newer atypical antipsychotic agents appear to have a broader spectrum of response with fewer side effects than the typical agents. These medications are available in tablet form and should be considered for patients who consent to oral medication. However, oral administration of a pharmacologic agent during an acute episode of agitation and psychosis is usually impossible. Ziprasidone (Geodon), aripiprazole (Abilify), and olanzapine (Zyprexa) are newer atypical antipsychotics currently approved in the United States for intramuscular injection.[33] For ziprasidone, the initial dose is 20 mg intramuscularly, and it can be repeated every 4 hours. It is more effective than haloperidol for sedation and with fewer extrapyramidal side effects, but it is not yet widely used in the emergency department setting.[34,35]

Benzodiazepines are effective in managing agitation in patients who have alcohol or sedative-hypnotic withdrawal, cocaine intoxication, or a contraindication to neuroleptic use. Benzodiazepines are helpful adjuncts to neuroleptic medication in providing rapid tranquilization, particularly for combativeness or severe agitation. Lorazepam (Ativan), 1 to 2 mg, is frequently mixed with haloperidol, 5 mg, in the same syringe and administered intramuscularly or intravenously for this purpose.[27] Benzodiazepines have also been shown to mitigate catatonic signs in schizophrenic patients.[36] Disadvantages of benzodiazepines are the need for repeated dosing and the close monitoring required for potential respiratory depression with large doses.[37]

Outpatient Management

The outpatient treatment of schizophrenia involves maintenance therapy with neuroleptic agents, family counseling, and social rehabilitation. Emergency physicians rarely prescribe outpatient

neuroleptic medications but should be familiar with complications associated with their long-term use.

Box 110-4 lists the most common neuroleptic medications currently used in the United States.[38-44] The mechanism of action is related to the blockade of dopamine receptors in the central nervous system, particularly dopamine D_2 receptors in the basal ganglia and limbic portions of the forebrain. The earlier, less potent drugs, of which chlorpromazine is the prototype, cause more pronounced sedation, orthostatic hypotension, and cardiovascular toxicity from a combination of anticholinergic, antihistaminic, and anti–alpha-adrenergic effects. More potent agents (e.g., haloperidol) are safer, especially in older patients, because of their relative lack of these adverse effects. However, these more potent drugs are associated with a higher incidence of extrapyramidal symptoms, such as dystonias, akathisia, akinesia, and rigidity.

The high frequency of severe adverse reactions, poor compliance by patients, and the large number of patients with symptoms refractory to traditional antipsychotic agents prompted the development of new alternative agents. These "atypical" neuroleptic agents block serotonin to a greater extent than dopamine does, resulting in a low incidence of extrapyramidal side effects. Clozapine is particularly effective in patients who have not responded to other antipsychotic drugs.[41] However, clozapine is expensive, has a side effect profile similar to that of the low-potency antipsychotic agents, and causes agranulocytosis in approximately 1% of patients.[39] It is recommended only for the treatment of patients with refractory psychosis. Olanzapine, quetiapine, and the newest agent, aripiprazole, are similar to clozapine but have fewer side effects and less risk of agranulocytosis.[38] Risperidone, another newer neuroleptic agent with improved effects on negative symptoms, has been found to be superior to haloperidol in several short-term trials.[42-45] The most recent FDA-approved drug (2006), paliperidone (Invega), is the active metabolite of risperidone. Unfortunately, the expense and unavailability of these newer antipsychotic agents limit their utility for treatment of acute psychosis in the emergency department. Ziprasidone, risperidone, and quetiapine have been associated with QT interval prolongation similar to that seen with droperidol and haloperidol but have not yet been found to be associated with sudden cardiac death.[46]

Because of the high incidence of extrapyramidal symptoms in patients treated with high-potency neuroleptics, it is common practice to administer antiparkinsonian drugs (e.g., benztropine, procyclidine, trihexyphenidyl) at the same time either to treat the adverse effects or to prevent them. Prophylactic treatment is most useful in patients with a history of extrapyramidal symptoms, those receiving large doses of high-potency antipsychotic agents, and those in whom the occurrence of these symptoms is likely to increase the risk of noncompliance.

Noncompliance with antipsychotic medication remains a leading cause of psychiatric hospitalization. Patients with recurrent psychotic relapses caused by noncompliance are candidates for treatment with long-acting injectable antipsychotic drugs, usually given every 2 weeks. Three such agents available in the United States are fluphenazine, risperidone, and haloperidol decanoate.[47]

Complications of Neuroleptic Drug Therapy

Dystonia

Acute dystonia, the most common adverse effect seen with neuroleptic agents, occurs in 1 to 5% of patients. This reaction is caused by a disruption of the dopaminergic-cholinergic balance in the nigrostriatal pathways of the basal ganglia, resulting in cholinergic dominance.[48] Dystonic reactions, which can occur at any point during long-term therapy and up to 48 hours after administration of neuroleptics in the emergency department, involve the sudden onset of involuntary contraction of the muscles of the face, neck, or back. The patient may have protrusion of the tongue (buccolingual crisis), deviation of the head to one side (acute torticollis), sustained upward deviation of the eyes (oculogyric crisis), extreme arching of the back (opisthotonos), and rarely laryngospasm. These symptoms tend to fluctuate, decreasing with voluntary activity and increasing under emotional stress, which occasionally misleads emergency physicians to believe they are factitious.

Dystonic reactions should be treated with intramuscular or intravenous benztropine (Cogentin), 1 to 2 mg, or diphenhydramine (Benadryl), 25 to 50 mg, which usually results in immediate reversal of symptoms. Patients should receive oral therapy with the same medication for 48 to 72 hours to prevent recurrent symptoms.[48]

Akathisia

Akathisia is a state of motor restlessness characterized by a physical need to be moving constantly. It occurs most often in middle-aged patients during the first few months of therapy. Patients usually pace the room and express a sense of inner tension that is not relieved by activity. If asked, they do not want to be constantly moving but feel physically compelled to do so. This reaction can easily be mistaken for a decompensating psychosis, leading to a vicious circle in which more medication is given to treat a side effect caused by the same drug. This misdiagnosis can be avoided by carefully evaluating the patient for the exacerbation of positive psychotic symptoms, which are not increased by akathisia. Akathisia is treated with beta-blockers (e.g., propranolol, 30-60 mg/day) and anticholinergic drugs (e.g., benztropine, 1 mg twice to four times daily). A new potential agent for the treatment of akathisia is glycine, a nonessential amino acid that stimulates glutamatergic neurotransmission.[49] In addition, if possible, the dosage of the antipsychotic agent should be lowered or replaced with another drug.

Pseudoparkinsonism and Akinesia

A clinical picture can occur that may be indistinguishable from Parkinson's disease, particularly in elderly patients during the first month of therapy. Treatment with anticholinergic agents (e.g., benztropine) or antiparkinsonian drugs is usually effective. Akinesia, which is characterized by immobility, withdrawal, and lack of motivation, may be mistaken for a postpsychotic depression. It

www.ketabpezeshki.com 66485457-66963820

is responsive to antiparkinsonian drugs, but symptoms usually resolve gradually over time.

Tardive Dyskinesia

Tardive dyskinesia usually appears after several years of neuroleptic drug treatment and is characterized by involuntary movements, especially of the face and tongue, that are described as writhing, grimacing, and choreoathetoid in nature. The earliest manifestation is often a curling or twisting movement of the tongue. The onset of these symptoms can be falsely attributed to psychological factors because they intensify under emotional stress, fatigue, and voluntary activity and disappear with sleep.

The reported prevalence of tardive dyskinesia ranges from 0.5 to 70%, with a mean of 24%.[48] The incidence of the disorder appears to be directly related to the duration of treatment, total cumulative dosage, evidence of preexisting brain damage, and age of the patient. It is more common in elderly women and patients with associated mood disorders. For patients with mild symptoms, discontinuation or lowering of the dosage of antipsychotic agents, switching to a newer atypical neuroleptic agent, and cotreatment with benzodiazepines may reverse the symptoms. Patients with moderate to severe symptoms are difficult to treat, but some have variable degrees of improvement when they are treated with reserpine or tetrabenazine along with discontinuation of neuroleptic treatment.[48]

Orthostatic Hypotension

All antipsychotic agents can cause orthostatic hypotension, an effect related to alpha-adrenergic blockade. This complication is less common with the more potent agents (e.g., haloperidol). Typically, episodes are mild in severity and brief in duration. Symptomatic patients should be treated with oxygen, Trendelenburg's position, and intravenous fluid administration. Pressor agents (e.g., dopamine) should be used only for severe, symptomatic episodes that fail to respond to the previous measures. Agents with beta-agonist activity (e.g., epinephrine, isoproterenol) are contraindicated in these patients.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a life-threatening complication of neuroleptic drug treatment that affects 0.5 to 1% of patients.[50] It is seen with both typical and atypical neuroleptic agents and usually occurs in the first few weeks after initiation of treatment, but it can also be seen after a recent increase in drug dosage or after parenteral treatment with large doses of neuroleptic agents. NMS is characterized by high fever, severe muscle rigidity, altered consciousness, autonomic instability, and elevated serum creatine kinase levels and can be confused with serotonin syndrome. Additional complications can include respiratory failure, gastrointestinal hemorrhage, hepatic and renal failure, coagulopathy, and cardiovascular collapse.

The pathophysiologic mechanism of NMS is not well understood, but it is thought to be related to dopamine depletion in the central nervous system leading to defective thermoregulation in the hypothalamus. Predisposing factors include exhaustion, dehydration, and the use of long-acting depot neuroleptics. Treatment consists of recognition and discontinuation of the neuroleptic agent, temperature reduction, rehydration with intravenous fluids, and general supportive measures. Dantrolene, a direct-acting muscle relaxant, should be used in severe cases. It can be administered by continuous rapid intravenous push at a minimum initial dose of 1 mg/kg, repeated until symptoms subside or up to a maximum cumulative dose of 10 mg/kg. For severe symptoms, dopamine agonists, such as bromocriptine, levodopa, and amantadine, have shown encouraging results. Because of early recognition and treatment, mortality rates with NMS have decreased from 30% to less than 10%.[51]

DISPOSITION

The ultimate disposition of the acutely psychotic patient depends on the underlying cause of the psychosis, whether the patient is a danger to self or others, and the presence of social support in the community. Hospitalization is indicated for patients experiencing their first psychotic episode, for patients deemed to be a danger to themselves (suicidal) or others (homicidal), for patients who are grossly debilitated, for patients who are moderately debilitated but have no social support system within the community, and for patients with either functional or organic psychosis that does not clear with a brief period of treatment and observation in the emergency department. The decision to hospitalize psychotic patients is complex and imprecise and often must be made in a short period with limited information.

A psychiatric short-procedure unit offers a cost-effective alternative to hospitalization.[52] After stabilization, patients are moved from the emergency department to a separate treatment area, where they are treated for a period of 12 to 24 hours by a small staff of consultants.

KEY CONCEPTS

- In patients exhibiting abnormal behavior, an organic cause is suggested by new onset of symptoms in a patient older than 35 years, rapid onset of symptoms in a previously normal person, visual hallucinations, abnormal vital signs, and lethargy or disorientation.
- Physical restraints should be considered for patients who have violent behavior, verbally threaten staff, or demonstrate escalating agitation despite verbal attempts to calm them. Restraints should be removed after sedation has been achieved.
- Rapid tranquilization is best accomplished with the use of high-potency neuroleptics (e.g., haloperidol, ziprasidone). Benzodiazepines (e.g., lorazepam) are a helpful adjunct for patients with severe agitation.

Chapter 111

Mood Disorders

James L. Young and Douglas A. Rund

PERSPECTIVE

Mood is a subjective emotional state, and fluctuations in mood are expected, especially in response to the joys and sorrows of everyday life. Mood disorders, however, extend beyond these common emotional variations. Patients with mood disorders often present with impairment in functioning, often severe and with threats to life that include suicide, profound self-neglect, and impaired judgment. They are also associated with impaired physical, social, and family functioning as well as with psychological and physical pain and a negative perception of physical health. Patients with mood disorders are most often seen in general medical settings, including the emergency department (ED), often in crisis. One fourth to one third of ED patients screen positive for mood disorders.[1]

The *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, text revision (DSM-IV-TR), divides mood disorders into four broad categories[2]: (1) depressive disorders, (2) bipolar disorders, (3) mood disorder due to a general medical condition, and (4) substance-induced mood disorder. Because the specific pathophysiologic mechanisms of these disorders are not fully understood, they are categorized by groupings of symptoms that persist for defined lengths of time. As research into the biology, genetics, and treatment of mood disorders advances, we hope to one day be able to more clearly demonstrate the pathophysiologic abnormalities.

EPIDEMIOLOGY

Up to 50% of Americans will meet the criteria for a DSM-IV-TR disorder sometime in their life.[3] Mental health patients are the fastest growing group of patients presenting to the ED.[4] In 2007, 12.5% of the 94 million ED visits in the United States were for psychiatric reasons,[5] which was an increase from 5.4% in 2000.[6] The lifetime prevalence for mood disorders is estimated to be 20.8%.[3]

The World Health Organization ranks major depressive disorder as one of the most prevalent and disabling diseases in the world.[7] The 12-month prevalence for major depressive disorder is 5.28% and the lifetime prevalence is 13.23%.[8] Patients with major depressive disorder frequently have other comorbid mental health issues, including anxiety disorders (36.1% 12-month and 41.4% lifetime prevalence), personality disorders (37.9% 12-month and 30.8% lifetime prevalence), and substance use disorders (4.6% 12-month and 17.2% lifetime prevalence).[8]

Although it is less prevalent than major depressive disorder, bipolar disorder is a serious and potentially life-threatening illness. Up to 80% of patients with bipolar disorder will exhibit suicidal behavior, and 51% will attempt suicide.[9] Suicidal behavior can occur during all phases of bipolar disorder, but patients experiencing a depressed or a mixed episode are at higher risk, especially those with severe depressive symptoms and a sense of hopelessness.[10] Bipolar disorder is diagnosed on a spectrum, decreasing in severity from bipolar disorder type I, consisting of both depressive and manic episodes, to bipolar disorder type II, which has depressive and hypomanic episodes, to subthreshold bipolar disorder, such as cyclothymia and bipolar NOS (not otherwise specified). Bipolar disorder type I has a 0.6% 12-month prevalence and a 1.0% lifetime prevalence, bipolar disorder type II has a 0.8% 12-month prevalence and a 1.1% lifetime prevalence, and subthreshold bipolar disorder has a 1.4% 12-month prevalence and a 2.4% lifetime prevalence.[11]

Most of the disability caused by bipolar disorder occurs during the depressive phase of the illness. On average, patients with bipolar disorder spend 30% of their time in a depressive phase, 10% in a manic phase, and 6% in a mixed phase.[12]

PRINCIPLES OF DISEASE

The pathophysiology of the mood disorders is not well established, but quite a bit is known about the neurophysiology, genetics, and psychosocial aspects of the disorders.

Neurophysiology

The immediate effects of most available antidepressants are to increase the availability and activity of serotonin and norepinephrine in the synapse with subsequent stimulation of the postsynaptic neuron. This is done by direct binding to the presynaptic and postsynaptic receptors, blocking reuptake of the neurotransmitter or inhibiting the enzymatic breakdown of the neurotransmitter. Because norepinephrine and serotonin systems traverse large portions of the brain, one hypothesis is that a monoamine deficiency is a cause of depression. There is a risk in deriving a theory from the mechanism of action of available antidepressants, but there is research to support the monoamine deficiency hypothesis. Positron emission tomography (PET) scans have demonstrated a 30% increase in TPH-2, a brain-specific tryptophan hydroxylase enzyme in some depressed patients.[13] Studies demonstrate that depletion of oral tryptophan and tyrosine, amino acids essential for the production of serotonin and norepinephrine, respectively, can induce a depressive episode in subjects with a history of depression but not in healthy controls.[14] Numerous studies of monoamine metabolite levels in cerebrospinal fluid, plasma, urine, and postmortem brains of patients with depression did not reliably demonstrate a monoamine deficiency, indicating that there could be downstream effects involving

www.ketabpezeshki.com 66485457-66963820

second-messenger systems such as cyclic adenosine monophosphate and phosphatidylinositol.[15]

Other neurotransmitter systems may play a role in the development of depression. A study using magnetic resonance spectroscopy demonstrated decreased levels of both glutamate and γ-aminobutyric acid in the prefrontal cortex of depressed subjects.[16] Intravenous ketamine, an *N*-methyl-D-aspartate (NMDA) antagonist, induces a rapid antidepressant effect[17] and suggests a role for glutamate in the pathophysiologic process of depression. This is important because the excitotoxic effects of glutamate can lead to neuronal loss and atrophy of some brain regions.[18] The brain relies on the actions of protective and regenerative cytokines, such as brain-derived neurotrophic factor (BDNF), and all of the known antidepressants and electroconvulsive therapy raise levels of BDNF and subsequently result in neurogenesis of certain brain regions, such as the hippocampus. Sleep deprivation and light therapy both have antidepressant effects, which suggests circadian rhythm abnormalities as a contributing mechanism for depression.[15,19,20] A novel antidepressant under investigation suggests a role for the melatonergic system and abnormalities in circadian rhythms.[21] Other theories include decreased neurosteroid synthesis, impaired endogenous opioid functioning, monoamine-acetylcholine imbalance, inflammatory effects of cytokines, and dysfunction of specific brain structures and circuits.[15]

The neurophysiology of bipolar disorder is less understood than that of unipolar depression, in part because of the fluctuating mood states and the heterogeneity of the disorder. Bipolar disorder may in part arise from abnormalities in the connections within and between structures in the brain.[22] Specifically implicated are circuits interconnecting the amygdala, hypothalamus, striatum, and subdivisions of the frontal cortex, all of which are involved in both the generation and regulation of emotion.[22]

Neuroanatomy

Neuroimaging studies of the brain suggest that abnormalities in certain areas and the interconnections between those areas may be involved in the mood disorders. A common magnetic resonance imaging (MRI) finding in patients with mood disorders, especially bipolar disorder, is an increased occurrence of subcortical hyperintensities in areas such as the periventricular areas, basal ganglia, and thalamus.[23] High-resolution MRI demonstrates reduced volumes in the hippocampus, orbital cortex, and anterior cingulate. These findings are associated with more severe illness, bipolar disorder, and increased cortisol levels.[23] Volume reduction in the hippocampus is associated with high illness chronicity.[23]

PET scans demonstrate a global reduction of glucose metabolism in the anterior regions of the brain, such as the dorsolateral prefrontal cortex. These findings are mood state dependent and are seen in both unipolar and bipolar depression. Patients in a depressed episode have lower relative functioning on the left side of the brain, and those who are hypomanic or manic have lower relative functioning on the right side of the brain.[23]

The amygdala is a clustering of nuclei that process emotional stimuli, especially fear, anger, and sadness. Functional neuroimaging suggests that amygdala activity is increased when the subject is exposed to emotionally relevant stimuli.[23] It has connections throughout the brain that regulate anticipatory anxiety (bed nucleus of the stria terminalis), cortisol release (hypothalamus), attention and mood (nucleus basalis of Meynert, locus ceruleus, ventral tegmental area), and sympathetic arousal (periaqueductal gray).[18] A decreased amygdala volume has been associated with unipolar depression.[18] There is decreased amygdala volume in children and adolescents with bipolar disorder and increased volume in adults with bipolar disorder.[18]

Endocrine System

The perception of stress in the environment by the cerebral cortex and the amygdala activates circuits and structures in the brain to cause physiologic changes such as increased alertness, decreased appetite, increased heart rate, and activation of the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis may play a role in depression, especially in cases of early childhood and chronic stress.

Activation of the HPA axis releases corticotropin-releasing hormone (CRH) from the hypothalamus. This results in a release of corticotropin (ACTH) from the anterior pituitary, which enters the bloodstream and stimulates release of cortisol from the adrenal glands. Cortisol then provides negative feedback to the hypothalamus and the pituitary to decrease the secretion of CRH and corticotropin, respectively.

There is evidence that CRH and cortisol play a role in depression. Although not specific, patients with depression may have increased levels of free cortisol in the plasma, cerebrospinal fluid, and urine.[24] Increased CRH has been demonstrated in cerebrospinal fluid, and increased levels of CRH messenger RNA and protein have been demonstrated in limbic brain regions.[24] Also, some patients with melancholic or psychotic depression have been shown to have an overactive HPA axis demonstrated by an inability of dosed dexamethasone to suppress cortisol release.[25] Although none of these measures is reliable as a diagnostic tool (e.g., the dexamethasone suppression test has been shown to be 90% sensitive for detection of depression but only 30-50% specific), successful treatment to remission has been shown to reverse some of these abnormalities.[24,26]

Genetics

Genetic vulnerability to mood disorders has not been traced to a single gene. It is likely to be due to the additive effects of many genes and environmental influences on how these genes are expressed.[27]

Major depressive disorder has a heritability of 37 to 38%,[28] lower than the heritability of bipolar disorder.[15] The heritability of major depressive disorder is higher in women than in men[28] and may be higher in early-onset, more severe, and recurrent forms of the disorder.[15] Genetic linkage studies have identified various chromosomal regions that are of interest in major depressive disorder, but not all of these have been consistently replicated.[15] There may also be some environmental factors that could have epigenetic effects.[15] One example of this is the region that codes for 5-HTT, a serotonin transporter protein. Individuals with one or more copies of the short allele of the 5-HTT promoter polymorphism have been shown in some but not all studies to be more prone to depression and suicidality when they are faced with an adverse life event compared with those with only the long allele.[27]

Bipolar disorder is one of the most heritable medical illnesses.[29] Bipolar disorder has a heritability of 80 to 85% and a monozygotic twin concordance of 40 to 45%.[29] There is also considerable overlap between the heritability of bipolar disorder and other DSM-IV-TR diagnoses. First-degree relatives of patients with bipolar disorder have an increased risk for both bipolar disorder and unipolar depression, but first-degree relatives of patients with unipolar depression do not have increased bipolar risk.[29] There is also overlap of genetic risk between bipolar disorder and schizophrenia.[29] Several different genes and linkage studies have been investigated, but the results have been inconsistent.[29]

Psychosocial Factors

The etiology of most psychiatric problems, including the mood disorders, involves complex interactions between both biologic

www.ketabpezeshki.com 66485457-66963820

and psychosocial factors.[30] The complex neural mechanism that regulates mood responds to and is modified by each person's experience, including events in early childhood, reward and punishment during growth and development, interpersonal relationships, and various kinds of loss. Psychosocial theories of mood disorder form the basis for psychotherapy.

Stressful Life Events

Environmental stress and adverse life events, such as parental neglect, sexual and physical abuse, and death of a loved one, have been shown to play a role in the onset of a mood episode as well as in the development and course of the mood disorders.[30] Neuroanatomic changes, such as decreased hippocampal volume and increased amygdala volume, and the correlation between the mechanisms of depression and molecular mechanisms of neuroplasticity suggest that stress has an adverse effect on the brain.[31] This supports the finding that a stressful life event is more likely to precede a first mood episode than subsequent episodes in both major depressive disorder and bipolar disorder.[32] Stressful events that patients perceive as reflections on their self-esteem are more likely to trigger mood episodes. Because many who are exposed to severe stressful life events do not develop mood disorders, it is likely that environmental, psychological, and social factors affect brain neurophysiology in susceptible individuals.[30] This is supported by models such as the activation of the HPA axis and increased susceptibility in those with a short 5-HTT allele described earlier.

Cognitive-Behavioral Theory

The cognitive model was first described by Aaron Beck and is the basis for cognitive-behavioral therapy. The cognitive theory looks at how individuals organize and interpret their experiences. These are called schemas. Those prone to depression develop depressogenic schemata composed of cognitive distortions, such as a tendency to focus on the negative, and overgeneralization. Beck proposed that those with depression have a negative cognitive triad composed of disparaging views about themselves, views of the world as hostile and demanding, and views that that the future will bring further suffering and failure.[32]

The concept of "learned helplessness" was developed on the observation that animals subject to repeated noxious stimuli, such as electric shock, and blocked from escape eventually stop trying to escape. They become apathetic, even when escape becomes available.[33] This concept was later applied to humans and adapted to construct a behavioral mode of therapy for depression.

The Interpersonal Theory

The interpersonal theory of depression emphasizes guilt, disputes between partners and family members, role transitions in families and relationships, and problems with social skills necessary to sustain a fulfilling relationship.

Psychodynamic Theory

The psychodynamic model was first developed by Sigmund Freud and later extended and modified by others, such as Karl Abraham and Melanie Klein. Basic tenets of this theory are that early childhood experiences during key developmental stages can predispose some individuals, depression can be linked to real or imagined loss, introjection of lost objects can be used as a defense against feelings of loss, and feelings of anger can be directed inward toward the self.[32]

Box 111-1 Summary of DSM-IV-TR Criteria for a Major Depressive Episode

A. Five or more of the following symptoms have been present almost every day during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
   Note: Do not include symptoms caused by a general medical condition, and do not include mood-incongruent delusions or hallucinations.
   1. Depressed mood (can be irritable mood in children and adolescents)
   2. Loss of interest or pleasure in activities
   3. Significant weight loss when not dieting or weight gain, or decrease or increase in appetite
   4. Insomnia or hypersomnia
   5. Psychomotor agitation or retardation
   6. Fatigue or loss of energy
   7. Feelings of worthlessness, or excessive or inappropriate guilt
   8. Diminished ability to think or concentrate, or indecisiveness
   9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation, or a suicide plan or attempt

B. Symptoms do not meet criteria for a "mixed episode."

C. Symptoms cause clinically significant distress or impairment in social, occupational, or other functioning.

D. Symptoms are not caused by direct physiologic effects of a substance (e.g., drug of abuse, medication) or a general medical condition (e.g., hypothyroidism).

E. Symptoms are not better accounted for by bereavement; after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Modified from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

CLINICAL FEATURES

Major Depressive Disorder

Major depressive disorder is characterized by one or more major depressive episodes, as defined by DSM-IV-TR criteria (Boxes 111-1 and 111-2), and a lifelong absence of manic episodes. A major depressive episode is characterized by disturbances in four major areas: mood, psychomotor activity, cognition, and vegetative function.[34] The patient must have at least five symptoms for a minimum of 2 weeks.

Mood Disturbances

Patients in a depressed state often feel profoundly hopeless and helpless. They may describe feeling anguished, sad, gloomy, dejected, unhappy, discouraged, or in low spirits. In addition, they may also experience feelings of anxiety and irritability. Those in a profound state of depression may not have the capacity to feel any emotion at all.

Depression can also be manifested as a decreased capacity to experience pleasure or interest in pleasurable or satisfying activities. Patients may have stopped doing formerly pleasurable activities entirely. This loss of interest and hedonic capacity is known as anhedonia.

The patient must exhibit a depressed mood or anhedonia to meet DSM-IV-TR criteria for a diagnosis of a depressive episode.[2]

Sleep amount increased or decreased
Interest (anhedonia)
Guilt
Energy level decreased
Concentration decreased
Appetite increased or decreased
Psychomotor activity increased or decreased
Suicidal ideation

Mnemonic for the Symptoms of Mania

DIG FAST
Distractibility
Irritability
Grandiosity
Flight of ideas
Activity increased
Sleeplessness
Thoughtlessness (impulsivity, increased risk taking)

Disturbances in Psychomotor Activity

Physical activity in depression can be either increased or decreased. Psychomotor retardation is a significant slowing of physical activity. The body language of depression may include a slumped posture and creased brow with arms folded, mouth turned down, and eyes closed or downcast. Depressed patients often describe feeling fatigued with a general lack of energy and motivation. Patients may also display psychomotor agitation, which can be manifested as fidgeting, pacing, hand wringing, rubbing of the skin, or restlessness.

Vegetative Disturbances

Vegetative symptoms include disturbances in three major areas: sleep, appetite, and sexual function. Depressed patients may complain of sleeping either too much or too little. Insomnia may be manifested as difficulty in falling asleep, frequent awakenings throughout the night, or early-morning wakening and inability to fall back to sleep. Depressed patients with hypersomnia may report sleeping 12 to 14 hours or more a day. Patients may fluctuate between insomnia and hypersomnia. Either sleep alteration may result in fatigue and decreased arousal. Alterations in appetite and eating patterns can also occur. Patients may eat too much or too little with resulting significant weight gain or loss during a short time. Loss of interest in sexual activity and impaired sexual functioning may also accompany depression, although this is not listed as a DSM-IV-TR criterion.

Thought Process and Content

Depressed patients often describe impaired concentration that may be manifested as diminished mental quickness, difficulty in maintaining attention and focus, and forgetfulness. Executive functioning, such as prioritization, problem solving, and planning, can be impaired. In severe cases, this results in a decreased ability to sufficiently take care of themselves or to perform basic activities of daily living, such as paying bills and the purchase and preparation of food.

Thought content tends to be negatively biased, such as recurrent thoughts of guilt, failure, worthlessness, and self-criticism.

Patients in a depressed episode are at increased risk for suicide. Suicidal thoughts may range from vague notions that life is not worth living to fully envisioned suicide plans with definitive intent to kill themselves. Severely depressed patients must be questioned about suicidal thoughts. Doing so does not increase the likelihood of a future attempt and provides an opening for a dialogue to address the patient's safety. Because patients are not often forthcoming with their thoughts on suicide, a thorough review of risk factors and protective factors needs to form the basis of clinical decisions for providing the necessary level of care.

Patients with severe depression may have psychotic symptoms. The hallucinations and delusions that accompany depression are usually mood congruent, meaning that the themes of the psychotic content are consistent with the depressed mood. An example could be voices saying extremely unpleasant things or punishing the patient for previous wrongs. The patient may report being "already dead" or feeling like "my insides have rotted away." Such hallucinations may suggest the Cotard syndrome, in which patients hold the belief that they do not exist or that they are dead.[35] Mood-incongruent psychotic symptoms do not reflect the mood as clearly and are less likely to occur in a depressed state. Examples are a fear that one is being followed or having one's thoughts controlled by external forces.

Masked Depression

Mood disorders may not be clear at presentation. The depressed patient may have only vague physical symptoms, such as weakness, fatigue, headache, or complaints of pain. Patients may not be aware of their depression and are often heavy users of medical care. Such symptoms may be the presenting features of a masked, or hidden, depression. Clues suggesting mood disturbance include the recent onset of a set of unusual behaviors, trouble at work or job loss, marital difficulties, and self-destructive behavior (e.g., substance abuse, sexual promiscuity).

Special Considerations

Children and Adolescents. Criteria for depression in children and adolescents are the same as for depression in adults. Depression in these age groups can, however, present differently from that in adults and is often misunderstood, masked in its presentation, or simply overlooked. Adequate treatment maximizes the child's potential and minimizes the serious negative impact that depression can have on multiple spheres of development.

Prepubertal children are more likely to have somatic complaints, psychomotor agitation, and mood-congruent hallucinations and less likely to have disturbances in sleep and appetite. Some children are misdiagnosed as having attention deficit disorder, especially if symptoms involve poor concentration, listlessness, agitation, and withdrawal from daily activities.[36]

Adolescents with depression may show increased oppositional behavior and substance abuse and tend to describe more irritability than depressed mood. Other characteristics are social withdrawal, increased rejection sensitivity, and decline in school performance. Some adolescents may be first diagnosed only with depression on receiving treatment for drug and alcohol problems.[36]

The selective serotonin reuptake inhibitors sertraline, fluoxetine, and citalopram are all effective in treating depression in this population. There is some evidence that treatment of adolescents and young adults may lead to increased suicidal ideation, and this has resulted in a Food and Drug Administration (FDA) "black box" warning. It is important that these patients be treated for depression but that the patients be monitored closely for suicidal thoughts, especially shortly after treatment with a selective serotonin reuptake inhibitor has started.[36]

www.ketabpezeshki.com 66485457-66963820

Geriatric. Age is not itself a risk factor for depression. However, depression is more common in older adults because of more frequent occurrences of loss and grief, comorbid health issues, and loss of autonomy. The elderly may have a tendency to report more somatic complaints than younger adults with depression do. They are also more vulnerable to development of melancholic depression, which is characterized by early morning awakening, diurnal variation in mood, low self-esteem, and low mood reactivity.[37]

Older depressed patients can also present with symptoms involving memory loss, inattention, withdrawal from daily activities, confusion, and lapses in personal and social hygiene that suggest dementia rather than depression. When such symptoms are from depression, the condition is called pseudodementia. Serious depression in elders is a highly treatable, reversible condition. It is essential to distinguish it from dementia for further diagnostic and therapeutic follow-up.

Other Depressive Disorders

Seasonal Affective Disorder. Seasonal affective disorder is not a separate mood disorder but a subclassification of major depressive disorder that is diagnosed when major depression occurs during seasons with less daylight (fall and winter), then either resolves or occasionally changes to manic episodes in seasons with more daylight, for at least 2 consecutive years. Melatonin, a hormone secreted in the brain and produced at high levels in the dark, has been implicated in the etiology of this disorder. Symptoms generally include hypersomnia, anergia, weight gain, and craving for carbohydrates. Phototherapy is an effective and safe treatment of seasonal depression.[38] Light exposure to the eyes seems to be essential, but the exact mechanism of action is still unknown.

Postpartum Depression. Symptoms of depression are common in the postnatal period. Up to 65% of mothers report some depressed mood after childbirth, often called postpartum blues. Symptoms are generally mild and transient, although in 10% of mothers, it may lead to a full-fledged episode of major depression. The signs and symptoms of postpartum depression are similar to those of a major depressive disorder, but the onset is within 4 weeks of delivery.[39]

Postpartum depression is more common in those who have a history of mood disorder, experience marital conflict, and have limited assistance with infant care.

Dysthymic Disorder. Dysthymic disorder is a long-standing, fluctuating, low-grade depression. Some features of a major depressive episode may be present, but marked changes in appetite or psychomotor disturbances are not typically observed. Depressed mood typically begins early in life, and the individual may report having always been depressed. Affected individuals generally are able to carry out their work assignments, but they gain little pleasure from the leisure activities others find enjoyable, such as recreation, time with family, or sexual activity. They typically experience significant impairment in interpersonal functioning.

Bipolar Disorders

Bipolar disorder is lifelong, with episodic exacerbation of symptoms and deterioration of function characterized by extreme mood episodes. Patients with bipolar disorder may require different forms and intensities of treatment at different stages of the illness. Bipolar I disorder includes at least one manic episode, and patients have typically had one or more major depressive episodes. Bipolar II disorder involves a hypomanic episode and at least one major depressive episode. A hypomanic episode includes the features of a manic episode without psychosis, marked impairment of function, or the need for hospitalization.

Box 111-3 Summary of DSM-IV-TR Criteria for a Manic Episode

A. Distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 2 weeks (or any duration if hospitalization is necessary).
B. During the period of mood disturbance, three or more of the following symptoms have persisted (four, if the mood is only irritable) and have been present to a significant degree:
  1. Inflated self-esteem or grandiosity
  2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
  3. More talkative than usual or pressure to keep talking
  4. Flight of ideas or subjective experience that thoughts are racing
  5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
  6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
  7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., buying sprees, sexual indiscretions, foolish investments)
C. Symptoms do not meet criteria for a "mixed episode."
D. Mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or social activities or to necessitate hospitalization to prevent harm to self or others, or psychotic features are present.
E. Symptoms are not caused by direct physiologic effects of a substance (e.g., drug of abuse, medication) or a general medical condition (e.g., hyperthyroidism).

Modified from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

Manic Episode

During a manic episode (Box 111-3), the disturbance in mood must be severe enough to include psychosis, the need for hospitalization, or marked impairment in functioning. Bipolar disorders are much less common than major depressive disorder. The overall prevalence of a manic episode is 1.6% in both women and men.[40]

In many cases, manic patients are brought to the ED by someone else (e.g., family, police, emergency medical services). Patients who are experiencing a manic episode may present as gregarious, humorous, and engaging, which may suddenly alternate with belligerence and irritability. Patients may display pressured speech, in which they keep talking, often rapidly and loudly without pauses between thoughts or sentences, and are difficult to interrupt. The thought process in mania is characterized by illogical associations and flight of ideas. An inflated self-esteem and grandiose delusions may lead them to also be argumentative, impatient, and condescending. Grandiosity often centers on very broad dramatic or universal themes, such as religion or politics. The patient may describe a massive undertaking, such as "uniting the world's churches" or "solving world poverty." These severe symptoms are usually accompanied by a profound lack of insight. Despite obvious altered behavior, impaired judgment, and poor impulse control, the patient may insist that there is nothing wrong or blame problems on others.

Manic patients have decreased or no need for sleep and typically report being awake for days. They may be involved in a massive project (e.g., writing a novel), may completely disregard consequences of actions, may have difficulty with spending (e.g., credit cards revoked), and may engage in risky behavior (e.g., sexual liaisons with strangers, risky driving). Whenever possible, a corroborating history should also be obtained from family or others who know of the patient's behavior.

www.ketabpezeshki.com 66485457-66963820

Manic patients may present to the ED as trauma patients, injured by an action reflecting the patient's grandiosity (e.g., attempting to fly), impulsivity, or belligerence (e.g., fighting, resisting arrest). A manic episode may be punctuated by abrupt periods of tearfulness and profound depression, including suicidal ideation. When depressive and manic features occur concurrently in such a manner, the disorder is termed mixed or bipolar, mixed phase.

Cyclothymic Disorder

Cyclothymic disorder is characterized by a life of mood swings of insufficient severity to meet criteria for a bipolar disorder. Persons with this disorder may have a chaotic life, characterized by frequent subclinical mood episodes, unstable relationships, and uneven school or work performance.

Mood Disorders Caused by a General Medical Condition

Certain medical illnesses have a well-known association with mood disorder (Box 111-4). In Parkinson's disease, electrical stimulation to a certain area of the substantia nigra alleviates symptoms of depression. Stimulation of an area only 2 mm away can cause acute reversible symptoms of depression, such as crying, not wanting to live, and hopelessness.[41] Parkinson's disease has a well-known association with depression, with up to 40% of patients demonstrating major depression.[42]

Certain malignant neoplasms have a well-known association with depression, including pancreatic carcinoma, brain neoplasm, and disseminated malignant disease (e.g., lymphoma).[43] Coronary artery disease,[44] myocardial infarction, stroke, end-stage renal disease, acquired immunodeficiency syndrome, several endocrine diseases, and connective tissue disease are also associated with major depressive disorder.[45] After a myocardial infarction, patients with depression experience a 3.5-fold increase in cardiovascular mortality compared with nondepressed patients.[46] The development of stroke, diabetes, and osteoporosis appears to be more likely in patients with depression than in those who are not depressed.[47,48]

Depression related to medical conditions may be different in some respects from primary depression and responds less favorably than primary depression to antidepressant medication.[49] Two significant issues arise in the assessment of patients with depression who have a serious medical illness. First, symptoms of depression must be distinguished from the symptoms and signs associated with serious medical illness (e.g., weight loss, loss of energy, slowing of activity, sleep disturbance, loss of ability to concentrate). Some experts have proposed that alternative criteria for depression caused by a general medical condition be substituted for DSM-IV-TR neurovegetative symptoms in patients with serious medical illness, such as depressed appearance, social withdrawal, pessimism or self-pity, anhedonia, and nonreactive mood. Second, it is important to determine if mood changes associated with terminal, rapidly progressive, or painful illness should be considered appropriate adjustment and grief. Although patients with such diseases may understandably be sad, most do not have major depression. The treatment of major depression in such patients should be considered and can greatly improve their quality of life.

Mood Disorders Caused by Medications or Other Substances

Certain medications are associated with symptoms of mood disorders (Box 111-5). Intoxication with or chronic heavy use of

alcohol, sedatives, hypnotics, anxiolytics, narcotics, and other depressants can cause symptoms of a major depressive episode. Stimulants such as cocaine, phencyclidine, hallucinogens, and amphetamines can cause symptoms of a manic episode. Mood disorder symptoms can also develop during withdrawal. To qualify for this diagnosis, the symptoms must not occur exclusively during a course of delirium, must cause significant distress or impairment of functioning, and must develop within a month of either substance intoxication or withdrawal.

When the mood disorder predates the period of substance abuse or lasts longer than 1 month after the period of abuse, the diagnosis may be an underlying mood disorder, such as a major depressive disorder or bipolar disorder, with a comorbid substance abuse or dependence diagnosis.

Substance abuse is often seen in patients with underlying depressive or bipolar conditions.

DIAGNOSTIC STRATEGIES

The initial history and physical examination should focus on the presenting complaints and evaluate the possibility that drug abuse, medications, or a general medical condition may be responsible for the patient's condition. The diagnosis of a mood disorder is based on history and observation of the patient's ability to relate to family and medical staff and style in relating to them. The patient's body language may be helpful. Precipitating events (e.g., loss of job or relationship), accompanying symptoms (e.g., hallucinations, delusions, anxiety disorder, mania), and suicidal ideation or intent should be assessed. The patient's history should be confirmed through interviews with family, friends, or eyewitnesses to the events that precipitated the ED visit. A tentative diagnosis can be established by use of DSM-IV-TR criteria. Laboratory tests to investigate medical conditions may be necessary (see Box 111-4), but no tests can confirm or exclude mood disorders.

DIFFERENTIAL CONSIDERATIONS

Medical disorders, medications, and substance abuse or withdrawal can either cause or mimic mood disorders. The patient who presents with agitation, for example, might have hypoxia, cocaine intoxication, or alcohol-sedative withdrawal. The patient with symptoms and signs of depression may have an unrecognized malignant neoplasm or sedative intoxication.

Patients taking antidepressant medication are often not being treated for depression as antidepressant medications are used to treat a variety of disorders: anxiety, obsessive-compulsive disorder, post-traumatic stress disorder, pain syndromes, smoking cessation, and vasodepressor syncope.

Grief and bereavement are normal human reactions to the acute loss of another person, health, social position, or job. The period of mourning is characterized by sadness, diminished sense of well-being (somatic complaints), sleeplessness, and sadness triggered by thoughts of the loss. Normal grief, however, does not include guilt, loss of self-esteem, feelings of worthlessness, suicidal intent, psychomotor retardation, or occupational dysfunction.

Adjustment disorders are behavioral or emotional disorders that occur in response to an identifiable stress or stressors. The emotional component can involve sadness, low self-esteem, suicidal behavior, hopelessness, helplessness, or other self-threatening behavior. Acute adjustment disorder occurs within 3 months of the stressor and does not last longer than 6 months. The stressors are typically not as severe as those precipitating bereavement reaction, and the responses are often more maladaptive. The teenager who ends a romantic relationship, for instance, may attempt a drug overdose in response to the stress. In such cases, adjustment disorder is a more likely diagnosis than major depressive episode. The pattern of recurrent maladaptive behavioral responses to stress may be lifelong, but the acute episode should resolve within 6 months.

Borderline personality disorder is characterized by unstable personal relationships, unstable self-image, and self-destructive behaviors. The disorder may include chronic feelings of emptiness, which may be misdiagnosed as depression, or lability of mood, which may be mistaken for mania or hypomania. These patients typically live lives of crisis and constant conflict.

Dementia can be confused with depression but is characterized by abnormal mental status, including abnormalities in tests of memory, calculation, and judgment. Delirium with waxing and waning sensorium, hallucinations, and delusions may involve disorganization, agitation, and restlessness, which might be considered features of mania or agitated depression.

Differential considerations for manic symptoms include the manic phase of bipolar disorder, stimulant abuse (e.g., cocaine, amphetamines), hallucinogen abuse, alcohol or sedative withdrawal, delirium, hyperthyroidism, other medical conditions causing agitation, brief reactive psychosis, schizoaffective disorder, and schizophrenia.

MANAGEMENT

Emergency Department Stabilization

The creation of a safe and stable environment for the patient should be the first priority in management. The patient with an acute manic episode may be disruptive, refuse medical evaluation, and make repeated attempts to leave the ED. The initial step in treating such a disruptive patient is to offer assistance in reducing the agitation (placing the patient in a single room, recommending medication). If this approach does not work, the patient may need to be placed in seclusion or restraints for his or her safety and that of others.

Initiation of treatment for a mood disorder is not typically done in the ED. An exception is the acute manic episode (or possibly a severe depressive episode with psychosis) with behavior so extreme that the patient or others are threatened. Such cases may involve significant hallucinations, delusions, and other features of psychoses. In such cases, intramuscular or oral administration of haloperidol with or without lorazepam can calm such patients. A typical regimen for "rapid tranquilization" is an initial dose of 5 mg haloperidol with 2 mg lorazepam intramuscularly and reassessment in 30 to 45 minutes for resolution of "target" symptoms such as agitation. A second dose is administered after 30 to 60 minutes as needed for improvement in hallucinations, delusions, agitation, or violent behavior.[50] Most patients respond after one or two doses. Benztropine (Cogentin), 1 to 2 mg, is often given initially to prevent extrapyramidal symptoms. Despite a black box FDA warning about prolongation of QT intervals and torsades de pointes, droperidol (2.5-5 mg) is a popular antipsychotic drug used effectively for agitation.[50]

The "atypical" antipsychotic medicines, including ziprasidone, risperidone, olanzapine, aripiprazole, and quetiapine, cause fewer of the side effects associated with conventional antipsychotic agents, such as acute dystonia, other extrapyramidal symptoms, and sedation. Oral doses should be offered first, and several agents, including risperidone, olanzapine, and aripiprazole, are available in rapidly dissolving tablet form. Three are available as an intramuscular injection: ziprasidone (Geodon), olanzapine (Zyprexa), and aripiprazole (Abilify). Ziprasidone 10 to 20 mg is effective; however, its use is limited to 40 mg per 24 hours. Olanzapine 2.5 to 10 mg effective but is associated with postural hypotension, and it is not recommended in combination with benzodiazepines because of the risk of hypoventilation. Aripiprazole is the newest agent and at doses of 9.75 to 15 mg seems to be the least sedating of the atypicals, but it is more likely to cause nausea and

www.ketabpezeshki.com 66485457-66963820

Box 111-6 Criteria for Hospitalization of Emergency Department Patient with Acute Psychiatric Episode

Patient demonstrates risk of suicide or homicide or of significant harm to self or others.
Patient lacks the capacity to cooperate with treatment.
Patient has inadequate psychosocial support for safe outpatient treatment and compliance.
Patient has a comorbid condition or complication that makes outpatient treatment unsafe (e.g., acute psychosis, bizarre behavior, need for detoxification).

vomiting.[51-56] Immediate psychiatric consultation should begin during the initiation of rapid tranquilization because patients undergoing rapid tranquilization will generally require hospitalization (Box 111-6).

Long-Term Treatment

Depression

Effective treatment modalities for depression are grouped into three broad categories: antidepressant medication, psychotherapy, and electroconvulsive therapy (ECT).

Antidepressant Therapy

Many effective antidepressants are available for first-episode uncomplicated major depression. After 4 to 6 weeks of therapy, the response rate is usually 60% or greater for all agents. However, 10 to 15% of patients quit medication trials,[57] and many patients in general medical practice are inadequately treated.[46]

Coexistent medical illness, psychotic or bipolar symptoms, substance use, and recurrent or refractory depressive symptoms should be considered in the choice of a medication for treatment of depression. The side effects of tricyclic antidepressants and monoamine oxidase inhibitors, along with strict dietary limitations, have led to the use of selective serotonin reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors for first-line treatment of depression. Side effects of these agents may include dizziness, sedation, peripheral anticholinergic symptoms, weight gain, sexual dysfunction, neurologic symptoms, insomnia, and anxiety. Another antidepressant, lithium, ECT, thyroid hormone, or atypical antipsychotic medication may be an adjunct in patients with treatment-resistant depression.

Psychotherapy

Brief psychotherapy is often initially used in patients with major depression. Interpersonal psychotherapy, psychodynamic psychotherapy, and group or family therapy can be used with some patients. Psychosocial therapeutic support typically includes community-based support groups that focus on specific individual, occupational, or family and marital issues that arise in depression and are amenable to group and supportive intervention.

Depressed patients benefit most from a combination of somatic therapy (medication or ECT) and psychotherapy. All patients with incomplete therapeutic response, recurrent depression, or comorbid conditions (e.g., anxiety or panic, substance abuse) should receive multimodal treatment.[58]

Electroconvulsive Therapy

ECT has a high therapeutic success rate and an excellent safety profile but is not a first-line treatment, in part because of an undeserved reputation among laypersons that ECT causes “permanent brain damage.” Indications for ECT include severe depression with malnutrition, severe psychosis with agitation, continuing significant suicide risk with ongoing suicidal behaviors, prolonged catatonia, and recurrent depression with a previously positive response to ECT. ECT is most often used as a second-line treatment of patients with moderate to severe depression who have not responded to trials of medication or who cannot tolerate the medication because of side effects or concurrent medical conditions.

KEY CONCEPTS

- Patients with apparent mood disorders should be evaluated for a medical disorder, medication effect, or drug use that can mimic both depression and mania.
- Mood disorders should be suspected in patients with multiple, vague, nonspecific complaints and in patients who are frequent, heavy users of medical care.
- The differentiation of depression and dementia in elders can be difficult but is important because depression often responds dramatically to treatment.
- Patients with mood disorders should be assessed for their potential for violence or self-harm before discharge.

Chapter 112

Anxiety Disorders

Rick McPheeters and Joshua L. Tobias

PERSPECTIVE

Acute anxiety and apprehension are common in emergency department (ED) patients. However, many medical conditions mimic anxiety disorders, and up to 42% of patients initially thought to have anxiety disorders are later found to have organic disease. Therefore, emergency physicians should thoroughly assess the anxious patient to identify and distinguish any underlying medical conditions and then appropriately treat that which is determined.[1]

Anxiety is a specific unpleasurable state of tension that forewarns the presence of danger, real or imagined, known or unrecognized, and is often verbalized as an intense feeling of worry. Vigilance is a positive consequence of anxiety that helps people to be alert to imminent danger. This awareness produces a greater ability to experience and manage extreme agitation.[1]

Up to a point, anxiety can improve performance with well-described adrenergic responses to stress that contribute to survival. However, when these responses go beyond a manageable point, further increases in anxiety add to the stress of the patient and lead to deterioration of performance and nonadaptive responses, resulting in pathologic anxiety (anxiety disorder). For instance, the threshold for pain may decrease, or the person may become more aware of body discomfort, with respiratory, cardiovascular, gastrointestinal, genitourinary, and neuromuscular complaints becoming prominent.[1]

The emergency physician should be able to distinguish between the anxiety and the illness and, if necessary, treat both entities. Because an anxiety state makes significant metabolic demands that can actually cause a marginally compensated organ system to fail, one should not assume anxiety to be purely functional; physical discomfort and illness often trigger an anxiety attack.

EPIDEMIOLOGY

Approximately 40 million Americans older than 18 years, nearly 20% of adults, are affected by anxiety disorders each year.[2] Anxiety disorders are among the most prevalent psychiatric disorders and are the most common psychiatric problems seen by primary care physicians, with 20% of these patients experiencing a type of anxiety disorder.[3] Many primary care patients have significant mood and anxiety symptoms, such as panic disorders, generalized anxiety disorders, and depression, but nearly half of these symptomatic patients never receive appropriate treatment.[4] Many patients would rather present with a physical complaint and try to disguise their anxiety than bear the perceived stigma associated with psychiatric complaints.[5] Patients with chronic illness and those who make frequent medical visits have higher rates of anxiety and depression. The prevalence of anxiety disorders surpasses that of any other mental health disorder, including substance abuse. There is a close relationship between alcohol abuse and anxiety disorders; those with anxiety disorders often turn to alcohol and substance abuse as a form of self-medication, and the substance abuser frequently has underlying anxiety in relation to the use of alcohol and drugs.[6]

PRINCIPLES OF DISEASE

The precise mechanisms underlying the development of anxiety have not been fully established. Noradrenergic, serotonergic, and other neurotransmitter systems all play a role in the body's response to stress. The serotonin system and the noradrenergic systems are common pathways implicated in anxiety. It is believed that low serotonin system activity and elevated noradrenergic system activity are involved, and thus selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have become a focus of treatment. The well-established effectiveness of benzodiazepines in the treatment of anxiety has led to the study of the γ-aminobutyric acid (GABA) system and its relationship to anxiety. GABA is the principal inhibitory neurotransmitter in the central nervous system, and benzodiazepines act on the $GABA_A$ receptors. Studies have focused on the role that corticosteroids may play in fear and anxiety. Steroids are thought to induce chemical changes in select neurons that strengthen or weaken certain neural pathways to affect behavior under stress.[7]

Anxiety reactions are also associated with aberrant metabolic changes induced by lactate infusion and hypersensitivity of the brainstem to carbon dioxide receptors. Studies focus on the regulatory centers found in the cerebral hemispheres. The hippocampus and the amygdala regulate emotion and memory and are important areas mediating an individual's response to fear.[8] Family research suggests genetic factors in anxiety, but the precise nature of the inherited vulnerability is unknown. Psychological and environmental factors, as outlined in psychodynamic, behavioral, and cognitive theories, also contribute in the generation of anxiety in biologically predisposed individuals.[8]

CLINICAL FEATURES

Many patients entering the ED experience anxiety, and for some this can be a significant clinical issue. The ED patient encounters many internal and external dangers: assaults on body integrity in the form of uncomfortable procedures and forced intimacy with strangers; the atmosphere of illness, pain, and death; and separation from loved ones and unfamiliar surroundings. In addition,

Amenorrhea
Menstrual discomfort

Neuromuscular
Tremor
Aching muscles
Prickling sensations
Headache
Dizziness, tinnitus

the patient may experience uncertainty about his or her illness, the implications that the illness may have on personal relationships and employment, and the financial burden that may accompany the illness.

The anxious patient can be a diagnostic challenge. Anxiety may represent the patient's reaction to medical illness or the medical setting, or it may be a manifestation of the physical disorder itself. The anxiety may also be an expression of an underlying psychiatric disorder. It may be difficult to make the distinction between anxiety as a symptom and anxiety as a syndrome in the ED. There is an overlap between normal situational anxiety and fear, anxiety-like symptoms resulting from a variety of organic disease states and their treatments, and the characteristic presentation of anxiety itself.

The physical symptoms of autonomic arousal (e.g., tachypnea, tachycardia, diaphoresis, lightheadedness) may be the only manifestation of anxiety (Box 112-1). Patients may complain only of overall poor health or vague subjective findings when they visit the physician. Classic panic disorder symptoms of chest pain, shortness of breath, and the sense of impending doom will often lead the patient to the ED, especially if it is the very first episode.[7] Anxiety associated with organic causes is more likely to be manifested with physical symptoms and less likely to be associated with avoidance behavior.[9]

DIFFERENTIAL CONSIDERATIONS

Medical Illness Presenting as Anxiety

Patients with anxiety disorders may present with apparent physical disease, and many physical diseases may be strongly associated with symptoms of anxiety. Somatic symptoms can be so prominent that they occupy most of the patient's attention, making it difficult to differentiate between a primary anxiety disorder and reactive anxiety to a situation or disease. Several factors help distinguish an organic anxiety syndrome from a primary anxiety disorder[10] (Box 112-2). Anxiety disorder classifications, in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), include anxiety caused by a general medical condition[11] (Box 112-3).

Anxious patients are frequently convinced that their problem is purely physical. The emergency physician should realize that the patient with anxiety is not in control of the symptoms and frequently cannot immediately identify the correct precipitant. Even though the patient may be uncomfortable, uncooperative, impatient, and unreasonable, triage medical personnel should recognize that the patient believes an illness truly exists and is not being consciously manipulative. Because anxiety may be the most obvious symptom of an underlying disease or condition, the patient should be evaluated for exacerbation of known preexisting disease as well as for onset of new illness since anxiety increases the risk of acute medical exacerbation of chronic illness.[12]

The classic scenarios of pulmonary embolism and hyperthyroidism causing anxiety are well documented. Cardiac disease studies indicate poorer outcomes in post–myocardial infarction patients with anxiety than in those without documented anxiety.

Box 112-2 Predictors of Organic Anxiety Syndrome

1. Onset of anxiety symptoms after the age of 35 years
2. Lack of personal or family history of an anxiety disorder
3. Lack of childhood history of significant anxiety, phobias, or separation anxiety
4. Lack of avoidance behavior
5. Absence of significant life events generating or exacerbating the anxiety symptoms
6. Poor response to antipanic agents

Box 112-3 Definitions of Anxiety Disorders

Panic attack is a discrete period in which there is a sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom.
Agoraphobia is an anxiety about, or avoidance of, places or situations from which escape might be difficult.
Panic disorder with agoraphobia is characterized by both recurrent, unexpected panic attacks and agoraphobia.
Agoraphobia without a history of panic disorder is characterized by the presence of agoraphobia and panic-like symptoms without a history of unexpected panic attacks.
Specific phobia is characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior.
Social phobia is characterized by clinically significant anxiety provoked by exposure to certain types of social or performance situations, often leading to avoidance behavior. Blushing is the cardinal characteristic symptom.
Obsessive-compulsive disorder is characterized by obsessions that cause marked anxiety or distress and by compulsions that serve to neutralize anxiety.
Post-traumatic stress disorder is characterized by experiencing of an extremely traumatic event, accompanied by symptoms of increased arousal and by avoidance of stimuli associated with trauma.
Acute stress disorder is characterized by symptoms similar to those of post-traumatic stress disorder that occur immediately in the aftermath of an extremely traumatic event.
Generalized anxiety disorder is characterized by at least 6 months of persistent and excessive anxiety and worry.
Anxiety disorder caused by a general medical condition is characterized by prominent symptoms of anxiety that are judged to be a direct physiologic consequence of a general medical condition.
Substance-induced anxiety disorder is characterized by prominent symptoms of anxiety that are judged to be a direct physiologic consequence of a drug of abuse or medication or toxin exposure.
Anxiety disorder not otherwise specified is included for coding (1) disorders with prominent anxiety or phobic avoidance that do not meet criteria for specific anxiety disorders and (2) anxiety symptoms with inadequate or contradictory information.

From American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

www.ketabpezeshki.com 66485457-66963820

Patients with respiratory diseases, such as asthma and chronic obstructive pulmonary disease, often have anxiety with their long-standing illnesses. In addition, many of the medications used to treat these illnesses may induce anxiety.[5] The most common organic cause of anxiety is alcohol and drug use from either intoxication or, more typically, withdrawal states.

Cardiac Diseases

Various psychiatric conditions may be manifested with complaints of chest pain. Approximately 25% of patients with chest pain who present to the ED have panic disorder. Their disorder often goes undiagnosed, resulting in multiple visits and expensive cardiac evaluations.[13] Some of the symptoms of *myocardial infarction* and *angina pectoris* may include crushing chest pain, shortness of breath, nausea, palpitations, heavy perspiration, and a feeling of impending death. These are also the primary symptoms of acute anxiety, but the pain is usually described as atypical, and patients are generally female and younger.[14] Because of the morbidity and mortality of cardiovascular disease, a patient warrants a full cardiac evaluation when the differentiation between myocardial infarction and acute anxiety is unclear.

Cardiac dysrhythmias can cause palpitations, discomfort, dizziness, respiratory distress, and fainting. An anxious patient with a panic disorder will frequently have similar symptoms. Fortunately, most dysrhythmias can be documented and characterized on cardiac monitors or by electrocardiography. *Mitral valve prolapse* syndrome can be associated with palpitations and panic attacks indistinguishable from a panic disorder. Benzodiazepines can be used to provide symptomatic relief to patients who experience chest pain. Studies have shown that benzodiazepines reduce anxiety, pain, and cardiovascular activation. It is hypothesized that secondary to the reduction in circulating catecholamines, benzodiazepines may cause coronary vasodilation, prevent dysrhythmias, and block platelet aggregation.[15]

Endocrine Diseases

The DSM-IV defines the most common endocrinologic conditions associated with anxiety states as hypoparathyroidism, hyperthyroidism and hypothyroidism, hypoglycemia, pheochromocytoma, and hyperadrenocorticism.[11] Anxiety is the predominant symptom in 20% of patients with *hypoparathyroidism*. Other symptoms include paresthesias, muscle cramps, muscle spasm, and tetany. Most cases are idiopathic or the result of surgical removal of the parathyroid glands during thyroidectomy. Studies indicate a higher incidence of anxiety in the subset of patients with surgically removed glands.[16] The diagnosis of hypoparathyroidism is suggested by a low serum calcium level and a high phosphate level and confirmed by a parathyroid hormone assay.

Anxiety symptoms are seen in up to 40% of diabetics, and 14% of diabetic patients suffer from anxiety disorders. There is evidence that diabetics who are treated with antianxiety medication not only reduce their anxiety but also decrease their glycosylated hemoglobin levels and high-density lipoprotein concentration.[17] Many patients with anxiety, somatoform, or characterologic disorders are convinced that they have *reactive hypoglycemia*. A normal result of a fingerstick blood glucose analysis done during an attack can exclude this diagnosis.

Pheochromocytomas are rare tumors that produce elevated levels of catecholamine in the body. Common symptoms include paroxysmal hypertension, headache, anxiety, sweating, flushing, abdominal and back pain, vomiting, and diarrhea. Pheochromocytoma attacks can be manifested just like panic attacks and can be precipitated by emotional stress. Whereas the sweating associated with pheochromocytoma attacks involves the whole body, the sweating in panic attacks is more likely to be confined to the hands, feet, and forehead. Elevated urinary catecholamine or plasma metanephrine levels can confirm a pheochromocytoma.[18]

Hyperthyroidism is one of the most frequently encountered endocrine diseases associated with anxiety. As with panic disorders, *hyperthyroidism* is associated with acute episodic anxiety. *Thyrotoxicosis* causes anxiety, palpitations, perspiration, hot skin, rapid pulse, active reflexes, diarrhea, weight loss, heat intolerance, proptosis, and lid lag.[19] Psychiatric presentations can be the first sign of *hypothyroidism*, occurring as the initial symptom in 2 to 12% of reported cases along with organic mental deficits. Anxiety and progressive mental slowing associated with diminished recent memory and speech deficits with diminished learning ability are the characteristic initial progression of symptoms. The severity of anxiety disorders in hypothyroid states relates to the rapidity of thyroid hormone level changes more than to the absolute levels. In general, checking of the serum thyroid-stimulating hormone and free thyroxine levels will suffice in the ED to establish the diagnosis of thyroid disease.[20]

Respiratory Diseases

Most conditions causing airway compromise or impairing gas exchange would never be mistaken for a psychiatric disorder. However, in some conditions that cause hypoxemia or hypercarbia, patients may present with significant anxiety, and up to a third of the patients with chronic obstructive pulmonary disease meet the criteria for anxiety disorder.[21]

Asthma is characterized by episodic attacks of dyspnea and often anxiety. Anxiety can also precipitate and prolong asthma attacks. Patients who have severe asthma are twice as likely to have an anxiety disorder and almost five times as likely to have a phobia compared with nonasthmatics. Severe asthmatics are almost five times as likely to have a panic disorder and about four times as likely to have a panic attack. Acute dyspnea from pure panic attack with good air movement and normal lung sounds is easily differentiated from an asthma attack, but studies consistently show that anxiety disorders increase asthma morbidity and mortality.[22]

Shortness of breath is a common complaint in the ED. When it is accompanied by anxiety, panic attacks or anxiety disorders may be high on the differential diagnosis, but so is pulmonary embolism. Acute shortness of breath in any patient should never be dismissed lightly, especially because pulmonary embolus can be manifested with only shortness of breath as the major symptom. The emergency physician can distinguish these patients by paying close attention to history and examination, assessing risk factors for thromboembolic disease, and using basic investigations (e.g., pulse oximetry, electrocardiography, chest radiography, and D-dimer assay) and further tests as indicated.[23]

Neurologic Disorders

Many neurologic conditions are associated with anxiety symptoms.[24-26] *Temporal lobe* seizures, complex partial seizures, tumors, arteriovenous malformation, and ischemia or infarction have been reported with panic attacks. Anxiety often accompanies a *transient ischemic attack* and may be the major symptom on presentation if the episode has resolved by the time the patient reaches the ED. The coexistence of anxiety disorders plays an important role in the prognosis and impairment of patients who have had *cerebral vascular accidents* with neurologic sequelae. Anxiety and depression are associated with left-hemispheric strokes, and anxiety alone is associated with right-hemispheric strokes. Finally, anxiety disorders occur in the aftermath of traumatic brain injury.[27] In *Huntington's disease*, anxiety is the most common prodromal symptom. Anxiety occurs in up to 40% of

www.ketabpezeshki.com 66485457-66963820

patients with *Parkinson's disease* and up to 37% of patients with *multiple sclerosis*. Similarly, anxiety symptoms are common in moderate *Alzheimer's disease*.

Drug Intoxication and Withdrawal States

Amphetamines, cocaine, and *sympathomimetic drugs* are abused for their stimulant and mind-altering properties. Patients often present to the ED agitated, anxious, or aggressive when these drugs are taken in large doses and with prolonged use. *Caffeine* is a common stimulant. Energy drinks and gourmet coffee represent a rapidly growing market in the United States. These drinks are packed with caffeine and the herbal equivalent guarana as well as *Ginkgo biloba*. Studies suggest that 240 to 300 mg of caffeine per day should be the upper limit of healthy consumption. Many energy drinks contain that amount in a single serving.[25] Although lower doses of caffeine can be pleasantly stimulating, higher doses may cause hyperalertness, hypervigilance, motor tension, tremors, gastrointestinal distress, and anxiety. The acute symptoms of caffeine intoxication and generalized anxiety disorder are almost identical. Stimulants such as ephedra and ephedrine-based compounds are found in many dietary supplements and listed by the herbal name of ma huang. Despite the Food and Drug Administration ban on ephedra-containing compounds in 2004, access to these drugs still exists over the Internet.

Many illicit drug users who use *marijuana* believe that the drug reduces their anxiety, but some experience a depersonalization that provokes severe anxiety, fearfulness, and agoraphobic symptoms. Lysergic acid diethylamide (*LSD*), phencyclidine (*PCP*), and *ecstasy* are hallucinogens that can produce anxiety and paranoia from chronic use or "bad trips." Flashbacks affect some users of LSD; the person may experience the symptoms of anxiety and paranoia weeks or months after use.[26]

Sedative-hypnotic drugs (e.g., benzodiazepines, barbiturates) are taken to relieve anxiety or sleeplessness, but their discontinuation can cause sedative withdrawal and rebound anxiety. The severity of the withdrawal syndrome depends on the drug, dosage, duration of use, and speed of elimination. In general, the intermediate-acting sedative-hypnotics (4 to 6 hours) cause the worst withdrawal symptoms. These symptoms include hyperalertness, motor tension, muscle aches, agitation, anxiety, insomnia, hyperactive reflexes, postural hypotension, tremulousness, nausea, vomiting, convulsions, delirium, and even death.

Benzodiazepine withdrawal is rarely fatal but can be very unpleasant. In anxious patients, severe rebound anxiety can occur after a few weeks' use of recommended therapeutic doses. Lorazepam and alprazolam are short-acting agents, and their abrupt discontinuation frequently causes panic attacks within 1 to 2 days. With longer-acting agents, withdrawal symptoms typically peak in about 1 week. Some people may experience this rebound as stimulating. Although antidepressants are rarely abused, their abrupt withdrawal can also cause an abstinence syndrome of insomnia, vivid nightmares, and extreme anxiety.[27]

Alcohol withdrawal, in alcohol-dependent individuals or heavy binge drinkers, can appear 6 to 12 hours after the last drink or significant reduction in consumption of alcohol. Patients often have detectable alcohol still in their systems at this time. Anxiety is one of the first and most prominent symptoms and is seen within 24 to 48 hours of the withdrawal state.[28]

Anxiety in Primary Psychiatric Disorders

Even in patients with known psychiatric illness, a panic disorder is a diagnosis of exclusion because several mental illnesses cause panic attacks as a secondary manifestation. The presence of panic often influences the treatment and outcome of the primary illness. Panic attacks can occur as part of a *bipolar* (*manic-depressive*) *disorder,* in either the manic or the depressed phase. In manic and hypomanic disorders, the patient's predominant affect is usually cheerful and euphoric but may also be dysphoric with irritability and extreme anxiety of panic proportions.[29]

Early in the course of schizophrenia, a patient will often experience panic attacks. Fearfulness, tension, agitation, immobility, disorganized thinking, dilated pupils, extreme insecurity, suspiciousness, and delusions of reference and persecution may characterize schizophrenic panic attacks. The hallucinations often have derogatory accusative content. Social anxiety is a common and disabling condition with schizophrenia that is unrelated to clinical psychotic symptoms.[30]

Patients with *somatoform disorders* report a variety of somatic symptoms, including panic attacks, and 68% report a history of anxiety. Patients claim to have most of the physical symptoms they are asked about, even when evidence excluding illness is presented to the patient. Fear and anxiety initiate, facilitate, and maintain many of the symptoms encountered in the somatoform patient. Patients with "pure" anxiety disorders tend to be hypochondriacal, whereas those with somatization are more likely to improve transiently with active medication or placebo but rarely respond so well that they stop seeking unnecessary medical attention. Patients with panic disorders, however, seek at least as much psychiatric attention as do those with somatoform disorders.[31]

Approximately 50% of patients with a primary panic disorder *major depression* and many others are bothered by some degree of depression in mood. Twenty percent of patients with depression have panic attacks, and the remainder have considerable anxiety. Depression with panic attacks responds less well to treatment. Agitated depression with anxiety and psychosis, sometimes called involutional melancholia, responds well to electroconvulsive therapy. Depression with anxiety and hostility responds well to antidepressants, but benzodiazepines can exacerbate symptoms.[32]

Post-traumatic stress disorder is characterized by the re-experiencing of an extremely traumatic event. The symptoms are closely related to and worsened by reminders of the trauma. The flashbacks, in which patients reexperience the original trauma, can have the same symptoms as panic attacks. These patients often avoid crowds or social situations.[33]

A panic disorder is one of the easier psychiatric diseases to feign because most of the symptoms can be duplicated by intentional hyperventilation. Functional hyperventilation can be distinguished from organic hyperventilation by its irregularity and interruptions by sighs. When there is doubt, formal psychiatric evaluation is indicated, particularly before a potentially dangerous or addictive drug therapy is prescribed.

A *phobia* is an irrational fear that results in avoidance. It is considered normal in children because the objects of fear tend to be things that seem dangerous to a child (e.g., spiders, snakes, enclosed places, the dark). Phobia becomes a disorder when it interferes with day-to-day function in an individual's life. A *social phobia* is characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior. Social phobias prevent a patient from doing such activities as public speaking, performing, visiting, using public showers or restrooms, or eating in public places. *Agoraphobia* is a fear of being alone in public places. Nearly 75% of agoraphobic patients have panic attacks.[34] Those with panic attacks are more likely to seek treatment, whereas those with uncomplicated agoraphobia tend to stay at home. Agoraphobia without panic attacks may not differ fundamentally from other simple phobias. Most panic disorder patients have multiple phobias, including agoraphobia, which is believed to result from the panic patient's increasing attempts to avoid places or situations in which the panic attacks would be particularly inconvenient or difficult to control. Agoraphobic patients particularly avoid places from

www.ketabpezeshki.com 66485457-66963820

which escape would be difficult (e.g., bridges, crowded theaters). When they do attend theaters, they favor seats on the aisle and near the door. Panic attacks in agoraphobic patients are more likely to include fear of losing control, whereas those not associated with agoraphobia are more likely to include dyspnea and dizziness.[35]

An *obsessive-compulsive disorder* (OCD) is characterized by recurrent, obtrusive, unwanted thoughts (obsessions), such as fears of contamination, and compulsive behaviors or rituals (compulsions), such as handwashing or checking. OCD is classified as an anxiety disorder because (1) anxiety or tension is often associated with obsessions and resistance to compulsions, (2) anxiety or tension is often immediately relieved by yielding to compulsions, and (3) OCD often occurs in association with other anxiety disorders. In summary, the obsessions and intrusive thoughts increase anxiety and the compulsions and repetitive behaviors decrease anxiety but with significant disruption of one's life.[9]

MANAGEMENT

Initial Evaluation

The patient should first be placed in a quiet area for evaluation. Some patients calm down when they are removed from the chaotic ED environment. If the emergency physician encounters difficulty in calming the patient, supportive family members may help. A known and trusted face often helps anxious patients make order out of their inner turmoil. Prior discussion and clarification with the family are essential to elicit their support.[1]

Once the patient is calmed, a more formal evaluation can begin. The emergency physician should ask open-ended questions and observe the patient's responses carefully. Questions about drug or alcohol use should be delayed until rapport has been established. Reassurance should not be premature; this important interventional technique is more effective when it is delayed until after the patient's specific concerns are clarified.[1]

The extent of the medical workup for significant anxiety will depend on the age and health status of the patient, the nature of the anxiety, and the range and severity of associated symptoms. The anxiogenic effects of medications, including beta-adrenergic agonists, corticosteroids, thyroid hormones, and sympathomimetics, should be considered. Potential contributory medical illness (e.g., thyroid dysfunction, hypoglycemic episodes in diabetes, hyperparathyroidism, dysrhythmias, chronic obstructive pulmonary disease, seizure disorders), substance use (e.g., caffeine, amphetamines, cocaine), and withdrawal states (e.g., alcohol, sedative-hypnotics) should also be considered.

If a somatic concern is the major component of the acute anxiety attack, a physical examination with particular attention to the area of complaint is important, even when there is overwhelming evidence of a functional etiology to the patient's complaints. Anxiety attacks are stressful experiences in themselves and can cause deterioration in marginally compensated organ systems. Careful evaluation reassures the patient and avoids the problem of a premature "medical clearance." Abnormal vital signs should suggest an organic cause of the anxiety symptoms.[9]

Because of the physical nature of the symptoms, patients with anxiety and panic attacks often seek treatment in the ED rather than in a psychiatric setting. A calm manner and willingness to listen usually relieve some of the patient's initial anxiety. An anxiety or panic reaction may be precipitated by the loss of a significant relationship, a job, a living situation, or self-esteem as well as by physical illness or injury. Once the patient describes a trigger event, the emergency physician should restate it, as if experiencing a similar situation. This gives the patient authoritative approval to express embarrassing feelings. A patient who has frequent anxiety reactions is usually suggestible and will respond to reassurance. Conversely, an anxious or unsympathetic physician will only compound the problem.[1]

Even an apparently calm patient may communicate anxiety through worried looks, nervousness, pressured speech, or covert assaults on the physician's competence. In turn, the physician may empathetically respond to the patient's hidden anxiety by also becoming anxious. This is a strong clue that the patient's anxiety is real and significant. Without this self-awareness, physicians may focus on a patient's physical symptoms rather than on the irrational anxiety. The pressure to see patients quickly and to move them out of the ED expeditiously may result in limited interactions with patients, the misdiagnosis of anxiety disorders, and excessive and unnecessary medical workups. A careful medical evaluation is important, but excessive focus on unlikely purely organic illness suggests to the patient a reason to worry, avoids recognition of crucial psychological factors, and may increase anxiety and the severity of symptoms.

After organic illness, medication effects, and obvious psychiatric causes of the acute anxiety state have been ruled out, the physician should determine whether the anxiety has an external trigger. If the anxiety arises spontaneously without an identifiable stress, is unpredictable, and is accompanied by agoraphobia, an endogenous component is likely to be present, and such patients should be referred to a psychiatrist for evaluation and treatment. If the anxiety appears to be related to an identifiable external event or circumstance, the anxiety is exogenous, and patients should be encouraged to discuss their feelings with a mental health worker. Talking about fears allows anxious patients some sense of mastery and control over events. These patients often require ongoing advice, support, and assistance in mobilizing necessary resources from family members, friends, and social agencies to achieve realistic expectations.

Anxiety is common in the geriatric population; prevalence rates are conservatively estimated at 10%, with higher rates in patients with chronic illness. Anxiety disorders may be the most common psychiatric ailments experienced by elders, but this age group is the least studied of all patients.[36] Older patients with anxiety often have somatic complaints. They require a careful investigation for underlying medical illness, other psychiatric conditions, and use of over-the-counter and prescription drugs.

Pharmacologic Treatment

Before medication is prescribed, education of the patient about the illness is a key component in the treatment of anxiety disorders. Patients are often worried and confused about their illness. Reassurance that they are not alone, education about what to expect and that therapy is available, and involvement of family are all critical in the treatment of anxiety. Use of intravenous medication is rare but may be necessary when an anxiety state renders a patient so helpless and out of control that there is a significant threat to safety of self or others. Intravenous medication is also appropriate for the anxious patient experiencing a significant medical illness or undergoing a medical procedure. Lorazepam in small increments can be helpful in alleviating the anxiety associated with substance withdrawal states. Midazolam reduces anxiety and increases amnesia for ED procedures.

SSRIs have become the first-line treatment of most anxiety disorders because of their broad spectrum of efficacy and good tolerance by most patients. SSRIs have a lower potential for dependence and are safer than the previous classes of antidepressants and anxiolytics. This class of drugs includes fluoxetine, sertraline, fluvoxamine, paroxetine, citalopram, and sertraline. Improvement is usually seen in 3 to 4 weeks, but the medication may have to be adjusted. Initiation of this group of medications is often reserved for the mental health professional as it is important to start the patient with low doses of SSRIs and to arrange for frequent

short-term follow-ups because an initial increase in anxiety may be seen.

The SNRIs were initially developed for the treatment of depression, but certain members of this class have been found to be beneficial in the treatment of anxiety. Venlafaxine is indicated in the treatment of generalized anxiety disorder, panic disorder, and social phobias; duloxetine has an indication for generalized anxiety disorder.

In the past few years, emergency physicians and the public have become increasingly concerned about the growing use of benzodiazepines in the United States. More than 1 million Americans are physically dependent on sedatives. When sedatives are given in place of understanding, support, and intrapersonal therapies, patients are taught to rely on the external support of a pill rather than on inner resources.[8]

Benzodiazepines can be prescribed for motivated patients with acute exogenous anxiety for time-limited stress. Patients who are cooperative, employed, educated, married, and aware that their symptoms have a psychological basis are more likely to respond. Benzodiazepines are an attractive alternative to the delayed response of an SSRI when an immediate reduction of symptoms is desired or a short-term treatment is needed. Benzodiazepines can be given in one or two daily doses to make use of their short half-lives; alternatively, a bedtime dose may minimize daytime sedation and still manifest a daytime anxiolytic effect. Benzodiazepines should not be prescribed for more than a week. Patients who do not improve within a week are unlikely to benefit from the drug. Patients with a history of alcoholism or drug abuse, who are excessively and emotionally dependent, or who become anxious in response to normal stress are at greater risk of drug dependency and are not good candidates for this treatment from an emergency physician. Dependence and abstinence syndromes have been reported to occur with low doses of sedating drugs, especially if they are taken for more than 8 months. Short-acting benzodiazepines (e.g., lorazepam, oxazepam) should be prescribed at low dosages for patients with liver disease or organic brain syndrome and for those taking medications that either depress central nervous system function or inhibit benzodiazepine metabolism and clearance. Withdrawal rebound symptoms are more common with discontinuation of benzodiazepines than with other antianxiety treatments. Short-acting benzodiazepines produce a more severe abstinence syndrome when they are stopped abruptly, and thus many physicians prefer the longer-acting benzodiazepines.[7] For some patients, switching from a short-acting agent (e.g., alprazolam) to a long-acting agent (e.g., clonazepam) can be helpful before initiation of a taper.

Buspirone is a nonbenzodiazepine used in the treatment of generalized anxiety disorder. Buspirone does not appear to cause dependency; it is less sedating than benzodiazepines, and tolerance does not occur at therapeutic doses. It is the therapeutic lag in efficacy of 2 to 3 weeks that has limited the use of buspirone. It has had variable and sometimes disappointing results in clinical practice, particularly when it is used in patients with prior exposure to benzodiazepines.[36]

Monoamine oxidase inhibitors (MAOIs) demonstrate high effectiveness in the treatment of social phobia, panic, generalized anxiety disorders, OCD, and comorbid conditions (e.g., atypical depression). MAOIs (phenelzine and tranylcypromine) may be difficult to tolerate and require discipline and strict dietary restrictions, and thus they are rarely appropriate in the emergency setting.

Tricyclic antidepressants (TCAs) are effective for panic disorders and generalized anxiety disorders but are ineffective for social phobias and, with the exception of clomipramine, are largely ineffective for OCD as well. TCAs have been used effectively for depressive and anxiety symptoms associated with post-traumatic stress disorder. TCAs include imipramine, nortriptyline, desipramine, amitriptyline, and doxepin. The TCAs have been supplanted by the SSRIs and SNRIs as first-line interventions for the treatment of anxiety and depressive disorders.[37]

Patients with endogenous anxiety (panic attacks with or without agoraphobia) should be referred to a psychiatrist to establish a good therapeutic relationship before using anxiolytic medication. Benzodiazepines, tricyclics, SSRIs, SNRIs, and MAOIs are safe and effective in endogenously anxious patients who are under psychiatric care (Table 112-1). Recurrence rates of panic attacks are high when drug therapy is discontinued.[8]

Nonpharmacologic Therapy

Psychotherapies may be helpful for individuals whose psychological makeup, coping style, interpersonal dynamics, and situational stressors contribute to their pathologic anxiety. The use of supportive, insight-oriented family therapy is helpful when these factors appear prominently in the patient's presentation.[8]

Cognitive-behavioral therapy is predicated on the theory that the distress and impairment associated with anxiety and panic are mediated by maladaptive cognitive responses that promote anxiety and avoidance. The core components of cognitive-behavioral therapy for panic disorder include correction of cognitive misperceptions and overreactions to anxiety symptoms, breathing retraining, and muscle relaxation as well as exposure and desensitization to phobic situations. Cognitive-behavioral therapy is very effective but requires commitment from the patient.[8,9]

Meditation (e.g., Zen, yoga, transcendental) has been proposed by many authorities, but few clinical data support its efficacy in

www.ketabpezeshki.com 66485457-66963820

anxiety disorders. *Biofeedback* appears promising for the treatment of generalized anxiety disorder. *Hypnotic suggestion* may be effective because anxious patients tend to be cognitively scattered, unable to focus their attention, and highly suggestible. A hypnotic state can often be induced by specific stimuli.[38]

These nonpharmacologic techniques take anxious patients out of the future, about which they are frightened, and place them into the present. These techniques should be reinforced by the development of a physically and psychologically healthy lifestyle. A significant social support system not only protects against vulnerability to illness but also is highly anxiolytic. Regular exercise (e.g., dancing, swimming, bicycling, walking, jogging) also promotes tranquility. Encouragement of activity that focuses on hand-eye-ear coordination (e.g., painting, playing keyboard, needlework) helps anxious patients regain and maintain control by bringing them into the present.[1]

DISPOSITION

Many patients with anxiety-related symptoms can be effectively treated in the ED by the following approach:

1. Rule out organic illnesses as a cause of anxiety.
2. Evaluate for substance abuse and medications associated with anxiety.
3. Determine whether anxiety is endogenous (without outside trigger) or exogenous (after an outside trigger).
4. Clarify what is currently frightening the patient.
5. Evaluate the patient's capacity for self-awareness.
6. Assess techniques that have worked in the past.
7. Support coping skills.
8. Give the patient as much control over the care plan as feasible.
9. Select patients to start with a short course of benzodiazepines, and educate patients about treatment.
10. Apply adjunctive techniques as appropriate for the patient's personality and the physician's preference (e.g., hypnotic suggestion, breathing exercises).

Patients with a panic disorder associated with suicidal or homicidal ideation or with severe depression require urgent psychiatric attention and admission to the hospital. Other patients with suspected endogenous or severe exogenous anxiety disorders should be referred for psychiatric evaluation. The Anxiety and Depression Association of America can be contacted (240-485-1001) for a national registry of clinicians and treatment programs specializing in anxiety disorders or can be found online at www.adaa.org.

KEY CONCEPTS

- Anxiety may accompany the onset of serious disease, may have significant metabolic demands, and may cause a marginally compensated organ system to fail.
- As many as 42% of patients thought to have anxiety disorders are later found to have organic disease.
- Anxiety caused by physical illness is usually suggested by the patient's physical findings but may require adjunctive testing.
- Anxiety affects at least 10% of elderly patients.
- Intravenous medication may be necessary for patients who are a significant threat to themselves or others and for anxious patients with significant medical illness.
- Limited benzodiazepine therapy may be helpful for select patients with exogenous anxiety.

Chapter 113

Somatoform Disorders

Adria Ottoboni Winter

PERSPECTIVE

Patients occasionally present to the emergency department (ED) with myriad physical symptoms in the absence of signs of physical disease. Whereas some harbor underlying medical disorders, many suffer from somatoform disorders, in which they experience and communicate psychological distress as one or more physical symptoms.[1,2] These patients have persistent distress related to the symptoms that inhibits their ability to function. Even when a somatoform disorder is strongly suspected, emergency physicians are reluctant to attribute physical complaints to a psychiatric disorder for fear of missing the subtle presentation of physical disease.

Somatoform disorders are among the most prevalent of psychiatric disorders in the primary care setting, occurring in at least 10 to 15% of primary care patients.[3,4] The annual cost to evaluate these patients medically is estimated at $100 billion.[5]

Somatoform disorders are an enormous source of angst for physicians as they can easily frustrate even the best attempts to place human suffering into well-defined categories based on physical disease. Somatoform disorders are unlikely to be diagnosed in a single visit; in fact, a definitive diagnosis requires multiple visits and an in-depth knowledge of the patient. Nevertheless, proper diagnosis and treatment of patients with a somatoform disorder are essential; misidentification and mismanagement prolong the patient's suffering and add immensely to excess health care costs, with unnecessary diagnostic testing and hospitalization.[5]

CLINICAL FEATURES

Seven somatoform disorders are listed in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV): (1) somatization disorder, characterized by many physical complaints affecting many organ systems; (2) conversion disorder, characterized by one or two neurologic complaints; (3) hypochondriasis, characterized by patients' beliefs that they have a specific disease; (4) body dysmorphic disorder, characterized by a false belief or perception that a body part is defective; (5) pain disorder, characterized by symptoms of pain that are solely due to or exacerbated by psychological factors; (6) undifferentiated somatoform disorder, which includes somatoform disorders not otherwise described that have been present for 6 months or more; and (7) somatoform disorder not otherwise specified, for those somatoform symptoms that do not meet any of the criteria otherwise described and classified.[6]

The general category of somatoform disorders was first explicitly defined in the DSM-III and updated in the DSM-IV; its revision is pending in the DSM-V. The initial criteria were based on descriptions by Briquet and Purtell[7,8]; however, the initial perspectives on hysteria and hypochondriasis have changed markedly and are likely to continue to do so. There is ongoing controversy about whether the somatoform disorders require a reclassification because the diagnosis does not explain the etiology, nor does it predict treatment response.[9]

The phenomenon of somatization extends across a broad spectrum of expression, from mild stress-related symptoms to chronic debilitating presentations that destroy a patient's ability to function socially or occupationally.[10,11] Patients with an underlying somatoform disorder can be particularly frustrating for the emergency physician because they cannot be approached from the practical standpoint of cause and effect, which is the bedrock of training and analysis for most physicians. It is not unusual for physicians to think that patients with somatoform disorders have nonlegitimate disturbances and are using medical care to treat their underlying emotional needs, with the resulting mismatch in the patient-physician relationship.[12]

It is important to recognize when a patient has a somatoform disorder, if only to avoid multiple unnecessary and time-consuming tests; however, the diagnosis itself is typically one of exclusion. In addition, somatizers typically steadfastly insist that their symptoms are caused by serious physical disorders even in the presence of conclusive evidence to the contrary.[13]

Historically referred to as hysteria, somatization disorder was given the eponym Briquet's syndrome by Guze in 1975 to avoid the pejorative connotations associated with the traditional terms.[14,15] *Somatization disorder* is the prototypic somatoform presentation, differing from the other somatoform disorders in the multiplicity of complaints and organ systems affected. As the number of physical symptoms increases, so does the patient's functional impairment and distress.[16] Research has shown that patients with somatization are more likely to be women, nonwhite, and less educated than nonsomatizers.[17]

The diagnosis of somatization disorder requires several criteria (Box 113-1).[6] It can be summarized as a polysymptomatic disorder that begins before the age of 30 years; extends for a period of years; and is characterized by pain, gastrointestinal, sexual, and pseudoneurologic symptoms. Somatization disorder is restrictive and represents only a small subset of patients who have moderate yet clinically significant somatization.[18] Somatization disorder, as currently defined, is present in less than 0.5% of the general population and in 1 to 4% of patients who present in general practice.[19]

Once referred to as hysterical neurosis and originally described by Breuer and Freud,[20] *conversion disorder* is characterized by abnormalities or deficits in voluntary motor or sensory function that are medically unexplained, including pseudoseizures,

www.ketabpezeshki.com 66485457-66963820

Box 113-1 Diagnostic Criteria for Somatoform Disorders

Physical symptoms that are misinterpreted or exaggerated, not accounted for by a diagnosable illness
Symptoms are not intentionally feigned or produced

Somatization Disorder

Unexplained physical symptoms that are manifested before the age of 30 years, that last several years, and that result in treatment being sought with significant impairment in social, occupational, or other important areas of functioning
Presence of the following at any time during the course of the disorder:
Four pain symptoms
Two gastrointestinal tract symptoms
One sexual symptom
One pseudoneurologic symptom

Undifferentiated Somatoform Disorder

One or more physical symptoms that cause significant distress or impairment in functioning, lasting at least 6 months

Conversion Disorder

A single unexplained symptom affecting voluntary or sensory function that suggests a neurologic or general medical condition and is associated with psychological stressors

Pain Disorder

Pain symptom is the predominant focus, causing significant distress or impairment and associated with psychological factors that play a role in the perception and maintenance of pain

Hypochondriasis

Preoccupation with fear of having a serious medical condition

Body Dysmorphic Disorder

Preoccupation with real or imagined physical defect

Somatoform Disorder Not Otherwise Specified (NOS)

Somatoform symptoms that do not meet criteria for other somatoform disorders, including unexplained physical complaints less than 6 months in duration

Modified from Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000; and Oyama O, Paltoo C, Greengold J: Somatoform disorders. Am Fam Physician 76:1333-1338, 2007.

Box 113-2 Presentations of Conversion Disorder

1. Motor disturbances
   a. Tremors (that worsen when attention is called to the movements)
   b. Seizures (wild, thrashing, writhing, often mimicking copulation)
   c. Paralysis or paresis (often a monoplegia, stocking-glove weakness, with normal reflexes and limb circumferences)
   d. Aphonia (wherein the patient can whisper and cough normally and vocal cords move normally with respiration)
   e. Coordination disturbances
2. Sensory disturbances
   a. Anesthesia (the patient may not find this symptom disturbing)
   b. Blindness and tunnel vision[16,17]
3. An occasional patient may present with other non-neurologic symptoms, such as vomiting or pseudocyesis.[13]

pseudoparalysis, psychogenic movement disorders, and blindness. Typically, there is a sudden dramatic onset of a single symptom, simulating some nonpainful neurologic disorder for which there is no pathophysiologic or anatomic explanation.[6,21] In contrast to somatization disorder, conversion disorder typically revolves around a single physiologically impossible condition that is not under the patient's voluntary control but probably represents the patient's own perception of neurologic illness. Some symptoms provide gratification for unconscious dependency needs, whereas others may provide escape from painful emotional stimuli (e.g., hysterical paralysis in battle).[22,23] Conversion disorder tends to occur more often in young, naïve, and uneducated women, except for those in military service and industrial accidents.[23] Typical comorbid diagnoses include mood disorders, panic disorder, generalized anxiety disorder, post-traumatic stress disorder, dissociative disorders, social or specific phobias, and obsessive-compulsive disorders. Patients with conversion disorder often have a history of physical or sexual abuse[21,24] (Box 113-2).

According to DSM-IV, *pain disorder* requires psychological factors that are important in the onset, severity, exacerbation, or maintenance of that pain and is characterized by clinically significant pain in one or more anatomic sites.[6] The primary and often exclusive symptom is distressful pain that is not intentionally feigned, is persistent in nature, limits daily function, involves one or more organ systems, and cannot be pathophysiologically explained.[6,25]

The term *hypochondriasis* comes from *regio hypochondriaca,* a Latin term referring to the upper lateral region of the abdomen inferior to the costal cartilages, especially the area of the spleen, which early physicians presumed to be the seat of this disorder. Hypochondriasis is defined as the preoccupation, despite medical evaluation and physician reassurance, that one has a serious disease based on the misinterpretation of symptoms.[6] Patients must have a preoccupation with their symptoms for at least 6 months before the diagnosis can be made. These patients typically have four characteristics: (1) physical symptoms disproportionate to demonstrable organic disease; (2) fear of disease and a conviction that they are sick, leading to "illness-claiming behavior"; (3) preoccupation with their body; and (4) persistent and unsatisfying pursuit of medical care with a history of doctor shopping and an eventual return of symptoms.[26]

These unfortunate patients manifest both a heightened awareness and an unrealistic interpretation of normal physical signs or sensations, such as bowel habits, heartbeat, sweating, or peristalsis. These sensations are perceived as abnormal, noxious, and alarming, a phenomenon known as *amplification.*[27] These aberrant perceptions result in a chronic morbid preoccupation with body functions and a lingering fear of having a disease despite medical reassurance.[6,25,26] A distinguishing feature of hypochondriasis is the presence of real symptoms that are often confirmed by physical examination, but the patient exaggerates and misinterprets them.

Hypochondriasis is relatively common. Its prevalence in general medical practice ranges from 4 to 9%.[6] It has a peak incidence among men in their 30s and women in their 40s, affecting men and women equally.[28-30] Hypochondriacs have an increased sense of responsibility for and place a high value on their personal health and physical appearance. They have an acute sense of body vulnerability and a heightened aversion to death and aging.[31] There is a strong correlation between hypochondriasis and major depression.[32] A milder form of this disorder may be an exaggerated interest in body function and health.[33]

The hypochondriac complains at length and in detail, using medical jargon. Hypochondriacs often believe that they have lost control of their lives and have been described as "experts at defeating doctors in order to feel more powerful."[26] Consequently, physicians perceive hypochondriacal patients as more angry and hostile than other patients.[34] The diagnosis may be suggested when the physician feels "frustration, helplessness, or anger associated with a wish to be rid of the patient."[26,35]

www.ketabpezeshki.com 66485457-66963820

Reactive hypochondriasis, or transient hypochondriasis, is an acute response to a psychosocial stress or life crisis, such as an acute myocardial infarction, terminal illness, or recent loss of a family member. In contrast to true hypochondriasis, this form is reversible and does respond to reassurance.[26,33]

DIAGNOSTIC STRATEGIES

Physicians are often reluctant to include a somatoform disorder in their differential diagnosis when patients present to the ED with unexplained symptoms. Their dramatic presentations and persistent preoccupation with a multitude of symptoms can overwhelm even the most pragmatic diagnostician. Yet repetitive or extensive diagnostic testing rarely excludes organic disease with absolute certainty and may yield false-positive results, which prompts further unneeded testing.[36,37] Unfortunately, somatizing patients are more likely to have morbidity from repeated diagnostic tests than from an undiagnosed physical disease.[38,39] In addition, patients with somatoform disorders often find frustration not only with their symptoms but also with the excessive testing and ineffective treatments that occur concurrently.

Yielding to the temptation to institute further diagnostic procedures or interventions typically leads to a temporary improvement, closely followed by a renewal of symptoms and mutual physician-patient disappointment. This gives rise to inevitable dissatisfaction of the patient with the physician and vice versa, leading to an unsatisfactory parting of ways and a perpetuation of the doctor-shopping cycle.[40]

Managed care and capitated reimbursement have created an additional quandary by restricting the supply of care in a time of rising demands from patients whose symptoms are relatively minor.[41,42] The most effective diagnostic tool with somatizers is the interview. Evaluation starts with a thorough but focused history and, if available, a review of the patient's medical record. This is followed by a careful problem-oriented physical examination, with meticulous inspection of the area of complaint and simple or routine diagnostic testing, when appropriate, until one attains a reasonable level of diagnostic certainty.[42] Further investigations or hospital admissions should be initiated solely on the basis of new objective signs of disease and only after confirming that the tests have not previously been performed. A rule of thumb in considering ancillary tests is to order exactly what would be done if the patient were not a somatizer.[35,42] However, the clinician should resist the impassioned entreaties of the patient when it is clear that further complex or hazardous studies are unlikely to be productive.[28,29,42,43] Multiple medical and surgical consultations generally prove counterproductive. Hypochondriacs perceive this as a test of their claim to illness and respond simply by propagating and demonstrating symptoms with redoubled zeal.[26]

Discussion of the diagnosis of somatoform disorder with these patients is fraught with potential pitfalls, especially in the ED, but it can be managed with some careful forethought. Somatizing patients are keenly aware of diagnostic labels, and all therapeutic alliance will be lost if the physician even hints at the possibility that their symptoms are "all in their head." It is important to discuss the possibility of the disorder with the patient after any underlying medical causation has been ruled out to lay the groundwork for any future psychiatric consultation and treatment.[13,28,44]

DIFFERENTIAL CONSIDERATIONS

Distinguishing between the various somatoform disorders is less important than the diagnosis of treatable organic disease or the detection of anxiety and depression, which are both more common and more likely to respond to treatment. Coexistent depression or anxiety disorder should always be considered.[45,46] Compared with patients with long-standing complaints, patients with a relatively recent onset of somatization are more likely to have underlying but subtle signs of acute psychosis, organic brain syndrome, grief reaction, depression, or anxiety.

Depression

Approximately 50 to 70% of depressed patients consult their physician for various somatic complaints.[47] Depressed patients may not be aware of a depressed mood or may believe that their depression is secondary to the somatic symptoms.[46] As a result, depression is the psychiatric disorder most often mistaken for somatoform disorder.[25]

Although somatoform disorders often coexist with depression, the two conditions must be distinguished if possible. Depression is worse in the morning, better at night, and often associated with a positive family history. The patient is reluctant to describe the symptoms and has vegetative signs of depression (e.g., sleep disturbances, decreased appetite with weight loss, and loss of interest in normally enjoyable activities).[43,48] Pain is a common symptom, particularly headache and pain involving the back, chest, or pelvic area.[46,47] Patients with somatoform disorders, on the other hand, are worse at the end of the day, have a marked propensity to discuss their symptoms, do not usually have a family history, and show no vegetative signs.[26]

In general, elders do not have more physical symptoms than younger patients do. Multiple somatic complaints should not be dismissed as a normal consequence of aging but rather considered a symptom of another underlying problem, usually depression or medical disease. Older patients may communicate somatic complaints as a way of expressing anger and provoking guilt among family members.[30] Depression is discussed in more depth in Chapter 111.

Anxiety

Patients with acute anxiety often hyperventilate and frequently exhibit physical signs of increased sympathetic activity. They may be hypervigilant and irritable and may show signs of muscle tension.[26] They may offer a history of excessive worrying about their health, feeling "on edge" or irritable, having difficulty relaxing, sleeping poorly, or having trouble falling asleep, and report symptoms of headache, tingling, dizzy spells, and diarrhea.[48] Patients with somatoform disorders have a high prevalence of anxiety disorders, especially generalized anxiety disorder.[49] Anxiety disorders are discussed in more depth in Chapter 112.

Physical Illness

When patients with somatization disorder have true organic disease, their presentation is similar to that of other patients, with specific complaints, clear chronology, and objective findings that should be appropriately investigated.[50] Unfortunately, subjective reports of distress are often not dependable in these patients, and the physician should rely on more objective evidence, including physical examination and routine laboratory tests.[35] Multiple physical symptoms starting late in life are frequently the result of physical disease.[6] In addition, patients who have a short duration of symptoms are more likely to have organic disease.

Patients with conversion disorder who present with the acute onset of neurologic symptoms can be particularly challenging. For example, an anxious young woman with apparently severe neuromuscular weakness and findings on neurologic examination that are inconsistent with an identifiable lesion or disorder may be suffering from a conversion reaction or any number of rarely encountered neurologic disorders (Box 113-3). [25] It may, at times,

Box 113-3 Organic Diseases That May Be Mistaken for Somatoform Disorders

Endocrine disorders: hyperparathyroidism, thyroid disorders, Addison's disease, insulinoma, panhypopituitarism
Poisonings: botulism, carbon monoxide, heavy metals
Porphyria
Multiple sclerosis
Systemic lupus erythematosus
Wilson's disease
Myasthenia gravis
Guillain-Barré syndrome
Uremia

require imaging studies and both neurologic and psychiatric consultations to arrive at a clear diagnosis.

Factitious Disorder and Malingering

Patients with somatoform disorders are not deliberately feigning illness; they are exhibiting the result of an unconscious behavior modification. For a subset of patients, secondary gain is unintentionally secured from the sick role in the form of sympathy, encouragement, attention, support, and relief from responsibilities and challenges without significant loss of self-esteem.[33] In contrast, *factitious disorder* and *malingering* are both characterized by the intentional and conscious simulation, exaggeration, or self-induction of illness for an identifiable secondary gain.[51,52] Because such deception is difficult to uncover in the ED, these patients are often mistaken for having a somatoform disorder. Factitious disorder and malingering are discussed in more depth in Chapter 114.

MANAGEMENT

The symptoms of a somatoform disorder may provide a protective coping value for the patient, and the physician should be cautious about removing them without first providing adequate psychological support and treatment. Otherwise, new symptoms may arise to replace old ones. The external precipitating stress or cause of anxiety should be removed if possible. These patients require psychiatric evaluation and management,[28,29] and psychiatric consultation in the ED can be beneficial.[53]

For conversion disorder in particular, recurrence is common, but the prognosis associated with an individual episode is good and the likelihood of recovery from symptoms exceeds that of other somatoform disorders.[6,23,30] Factors associated with a good prognosis include good premorbid health; absence of organic illness or concomitant major psychiatric syndromes; acute and recent onset; definite precipitation by a stressful event; and presenting symptoms of paralysis, aphonia, or blindness.[6]

Reassurance

Young patients with no underlying medical or psychiatric illnesses who present with somatization in response to a clear psychosocial stress can often be reassured successfully with an appropriate explanation of their symptoms. Patients with chronic somatization, however, perceive this as an official denial of their sick role and are almost invariably unwilling to accept reassurance. Because they desire the acknowledgment and recognition that come with the designation of illness, which they think is rightfully theirs, they are disappointed when no pathologic condition is discovered. Conversely, they are elated when given a diagnosis, but they resist recovery because subconsciously the "specter of cure" poses a threat to their sick role.[33] Accordingly, attempts to cure the condition are countered with side effects, allergic reactions, and new symptoms. Such patients require another management strategy.

Legitimization of Symptoms

Most patients with chronic somatization interpret a psychological explanation for their symptoms as an accusation of lying or feeblemindedness. It is important to convince them that the physician believes in their symptoms and will not try to "talk them out of it." The priority is to listen and truly understand what the patient is feeling and trying to convey. Suffering is a subjective phenomenon and, in that sense, is genuine in these patients.[35] The physician should convey empathy for the patient's physical discomfort. If the physician acknowledges the legitimacy of the claim to illness and assures the somatizer of ongoing care, limits may be set on the patient's illness behavior.[26,28,29,42]

Patients should be allowed to tell their story without interruption. They should be told that they have an illness that causes them to experience many symptoms but that these symptoms will not lead to medical deterioration.[38,54] The physician should offer only guarded projections about chances for complete "cure" of the condition. Ironically, this may be better received by these patients than overly optimistic assurances because it serves to safeguard their sick role and shifts the physician away from an adversarial position.[42,43]

Diagnosis

Diagnostic labels are of critical importance for somatizers, but the precise meaning of the term should be clarified for the patient to avoid misinterpretation. Explanations for symptoms that incorporate somatic responses and descriptions, such as hyperventilation, tension headache, muscle tension, muscle strain, chest wall muscle spasm, and stress, may be better accepted than purely psychiatric diagnoses. This reassures the patient that the physician shares the belief that the symptoms result from socially acceptable ailments while allowing more in-depth explanations that incorporate the relationship of body function to psychological stress. This, in turn, serves as a preparation for future psychiatric consultation or psychotropic medication.[13,28,29,43]

At times, the best approach may be to share the diagnostic uncertainty with the patient, using such terms as "atypical pain" or "multiple complaints following injury." On a broader scale, managed care organizations can be encouraged to educate their enrollees about the process of somatization, the negative side effects of medications and other interventions, and the range of body symptoms in healthy people.[41]

Medications

Patients with somatoform disorder have a high affinity for medications and are reluctant to discontinue drugs, even those with no benefit.[26] Physicians should avoid drugs that produce an abstinence syndrome or dependence and those that cannot be safely continued indefinitely.[50] Pain medications, if given, should be prescribed on a regular schedule, not "as needed."[26] Patients with somatoform pain disorder may benefit significantly from treatment with antidepressants, including tricyclic antidepressants.[55] Patients with somatization disorder with major depression may also improve with pharmacologic management of the depression.[32]

Therapy should be kept simple and limited to exercise, diet, physical therapy, and vitamins when possible.[43] Hospitalization and narcotics should be avoided. Benign remedies, such as lotions, nutritional supplements, elastic bandages, and heating pads, may be helpful.[42,35] Drug regimens should be simplified and only the

www.ketabpezeshki.com 66485457-66963820

most distressing symptoms addressed. Before any type of symptomatic drug treatment is started, specific target symptoms should be identified. The goal is to restore function and to make the target symptoms tolerable, not to remove them completely. If patients request an increase in dosage or a stronger medication, they should be told to review their medications with their regular physician before any changes are made. Insistent patients should be informed that long-term opioid use is associated with significant adverse effects, especially constipation, sedation, impaired cognition, and progressive development of tolerance and addiction.[35]

Mental Health Consultation

Patients with somatoform disorders have difficulty in confronting their own emotions, view psychiatric evaluation as threatening to their sick role, and take offense at any suggestion that their fears or beliefs may be unwarranted.[56] They usually resist psychiatric consultation, which they interpret as an attempt to be "dumped on the psychiatrist."[26] Nevertheless, psychiatric consultation may be appropriate to confirm the diagnosis or to discuss medications, when the patient has coexistent manifestations of chronic depression or psychosis, when symptoms suddenly change or become bizarre, when the patient expresses suicidal ideation or severely disruptive behavior, when current management is not working, or when the patient requests psychotherapy.[26,28,29] Favorable prognostic indicators include youth, acute onset, concurrent anxiety or depression, and limited medical comorbidity.[57] Approximately one third of patients with conversion disorder also have major depression, and successful treatment of the depression may lead to improvement or resolution of the conversion disorder.

Many patients accept psychological treatment under the rubric of "stress management" as long as it targets physical symptoms and somatic distress.[42] Group therapy techniques presented as education rather than as psychotherapy have had some limited success.[58] Patients should be reassured that their relationship with the primary physician will continue to avoid the interpretation that the referral is an abandonment.

Physician Attitudes

The key to diagnosis and treatment of patients with somatoform disorder is effective and appropriate communication skills of the physician. Somatizing patients can present a challenge because it is tempting to point out to them that there is nothing "wrong" with them and that their symptoms need no treatment. Physicians caring for these patients predictably react with feelings of uncertainty, helplessness, anger, or guilt when they can find no physiologic process to explain the patient's distress. Patients with somatoform disorders can become as frustrated with their physician as the physician is with them. It is common for a patient with a somatoform disorder to be quickly labeled a "difficult patient" by the physician and staff.[59,60] Unfortunately, the frustration of working with these patients quickly overwhelms the physician's natural tendency toward compassion and can lead to a swift breakdown in communication. Despite the large number of distressing symptoms reported, physicians rarely demonstrate empathy with these patients.[61,62]

Treatment Goals

Somatizing patients, despite lack of objective pathophysiologic changes, are, in fact, patients who are in need of and benefit from tangible and effective help. For some, attaining invalid status enables them to be cared for and nurtured. It offers them a sense of self-importance and respect not otherwise available to them as well as an honorable release from noxious personal and vocational responsibilities and duties.[22] To attempt a cure poses a threat to this role, and unduly positive projections by physicians are therefore understandably met with disappointment, disbelief, and even thinly veiled reproaches about their professional competence.[42,43,63] Thus the goal of therapy should be control of disability and appropriate referrals rather than cure.[30,57] The course of management most likely to prove successful begins with the physician's performing a sympathetic and thorough problem-oriented history and physical examination, then offering the patient the paradoxical reassurance that he or she will probably always be ill. When pain is the dominant feature, the patient should not be promised complete relief; rather, a major task of the patient should be to "learn to live with some pain."[30]

Treatment goals should focus on modification of illness behavior and improvement of functional status.[22] Achievable endpoints include decreased frequency and urgency of medical use, in particular a reduction in ED and unscheduled office visits; avoidance of expensive and hazardous procedures; improved work or school performance; more social activities; and better personal relationships.[25,28,35]

These principles apply equally to children with somatoform disorders. Unnecessary tests and procedures, in addition to placing the patient at risk, may encourage somatization. Physician acknowledgment of the patient's suffering and family concerns, a "rehabilitative" approach emphasizing return to normal activities before definitive symptom relief, rewarding of healthy behavior and discouragement of the sick role, assumption by the patient of responsibility for coping with the symptoms, and treatment of coexistent anxiety or depression are the cornerstones of therapy.[64]

Patients with somatoform disorder have been described as the "least insightful, the least introspective and the least cognitively oriented patients one is likely to encounter."[50] Understanding of the link between emotional and somatic distress need not be a treatment goal for these patients, and insight-oriented psychotherapy is neither productive nor cost-effective.[30,35,42,50] On the other hand, both the physician and the patient can benefit by accepting fundamental alterations in the traditional paternalistic physician-patient relationship. Increasing responsibility for health and disease management should be incrementally turned over to the somatizing patient.[30]

DISPOSITION

Appropriate psychiatric referrals should be provided for the patient. Outpatient tests or hospitalization should be avoided unless clear objective signs indicate a need for diagnostic investigation or therapeutic intervention.[30,50]

As a rule, management is best carried out by a single primary care physician who becomes the gatekeeper for all medical consultation and care.* The patient should be told that no alarming findings have come to light, that further testing and additional medications are not indicated at this time, and that ongoing care and periodic reassessment are indicated and will be arranged. Patients with chronic somatization should initially be seen every 2 to 4 weeks, preferably by the primary care physician, even if their symptoms are stable. The visits should be on a time-contingent, not a need-contingent, basis. For the patient, this severs the association between medical contact and the necessity for worsening or additional symptoms and complaints. It also decreases the patient's fear of abandonment by the physician and permits repeated evaluation for early detection of objective signs of organic disease.[25,30] The patient seems to value the visit to the physician more highly than any treatment.[50]

KEY CONCEPTS

- The differential diagnosis of patients with apparent somatoform disorders includes depression, anxiety, factitious disorder, malingering, and true underlying physical disease.
- Patients with conversion disorder who present with the acute onset of neurologic symptoms can be particularly challenging. It may, at times, require imaging studies and both neurologic and psychiatric consultations to arrive at a clear diagnosis.
- The behavior of patients with somatoform disorders is unconsciously driven. They are not "faking" the symptoms or their distress.
- ED management of known or suspected somatoform disorders includes legitimization of symptoms, communication of compassion, and assurance that ongoing vigilance of the patient's medical condition will be arranged and maintained.
- Long-term cure of somatization disorder is unlikely. However, a steady state of symptom coping with improved function is an achievable goal. This can be done only in the primary care setting, not in the ED.
- In general, laboratory tests, specialty consultations, initiation of medications, and hospitalization should be avoided in patients with known or suspected somatoform disorders unless new objective clinical findings are found.
- Whenever possible, treatment decisions should be deferred to the patient's primary care physician.

Chapter 114

Factitious Disorders and Malingering

Jag S. Heer

PERSPECTIVE

Patients may present to the emergency department with symptoms that are simulated or intentionally produced. The reasons that cause this behavior define two distinct varieties: factitious disorders and malingering.

Factitious disorders are characterized by symptoms or signs that are intentionally produced or feigned by the patient in the absence of apparent external incentives.[1,2] Factitious disorders have been present throughout history. In the second century, Galen described Roman patients inducing and feigning vomiting and rectal bleeding.[3] Hector Gavin sought to categorize this behavior in 1834.[3] These patients constitute approximately 1% of general psychiatric referrals, but this percentage is lower than that seen in emergency medicine because these patients rarely accept psychiatric treatment.[1,4] Of patients referred to infectious disease specialists for fever of unknown origin, 9.3% of the disorders are factitious.[5] Between 5 and 20% of patients observed in epilepsy clinics have psychogenic seizures, and the number reaches 44% in some primary care settings.[6] Among patients submitting kidney stones for analysis, up to 3.5% are fraudulent.[7]

Munchausen syndrome, the most dramatic and exasperating of the factitious disorders, was originally described in 1951.[8] This fortunately rare syndrome takes its name from Baron Karl F. von Munchausen (1720-1797), a revered German military officer and noted raconteur who had his embellished life stories stolen and parodied in a 1785 pamphlet.[3] The diagnosis applies to only 10 to 20% of patients with factitious disorders.[1,9] Other names applied include the "hospital hobo syndrome" (patients wander from hospital to hospital seeking admission), peregrinating (wandering) problem patients, hospital addict, polysurgical addiction, laparotomaphilia migrans, Kopenickades syndrome, Ahasuerus syndrome, and hospital vagrant.[4,10,11]

Munchausen syndrome by proxy (MSBP), an especially pernicious variant that involves the simulation or production of factitious disease in children by a parent or caregiver, was first described in 1977.[12] There are approximately 1200 estimated new cases of MSBP per year in the United States.[3] The condition excludes straightforward physical abuse or neglect and simple failure to thrive; mere lying to cover up physical abuse is not MSBP.[13,14] The key discriminator is motive: the mother is making the child ill so that she can vicariously assume the sick role with all its benefits. The mortality rate from MSBP is 9 to 31%.[14,15] Children who die are generally younger than 3 years, and the most frequent causes of death are suffocation and poisoning.[14] Permanent disfigurement or permanent impairment of function resulting directly from induced disease or indirectly from invasive procedures, multiple medications, or major surgery occurs in at least 8% of these children.[14,16] Other names applied include Polle's syndrome (Polle was a child of Baron Munchausen who died mysteriously),[3,10] factitious disorder by proxy,[17] pediatric condition falsification,[18] and Meadow's syndrome.[2]

Malingering is the simulation of disease by the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives, such as avoidance of military conscription or duty, avoidance of work, obtainment of financial compensation, evasion of criminal prosecution, obtainment of drugs, gaining of hospital admission (for the purpose of obtaining free room and board), or securing of better living conditions.[2,19-21] The most common goal among such "patients" presenting to the emergency department is to obtain drugs, whereas in the office or clinic the gain is more commonly insurance payments or industrial injury settlements.[22] Because of underreporting the true incidence of malingering is difficult to gauge, but estimates include a 1% incidence among mental health patients in civilian clinical practice, 5% in the military, and as high as 10 to 20% among patients presenting in a litigious context.[20] The most likely conditions to be feigned are mild head injury, fibromyalgia, chronic fatigue syndrome, and chronic pain.[23]

CLINICAL FEATURES

Factitious Disorders

With a factitious disorder, the production of symptoms and signs is compulsive; the patient is unable to refrain from the behavior even when its risks are known. The behavior is voluntary only in the sense that it is deliberate and purposeful (intentional) but not in the sense that the acts can be fully controlled.[2] The underlying motivation for producing these deceptions, securing the sick role, is primarily unconscious.[9,24,25] Individuals who readily admit that they have produced their own injuries (e.g., self-mutilation) are not included in the category of factitious disorders.[17] Presentations may be acute, in response to an identifiable recent psychosocial stress (termination of romantic relationship, threats to self-esteem), or a chronic life pattern, reflective of the way in which the person deals with life in general.[26] The symptoms involved may be either psychological or physical.

Psychological Symptoms

This disorder is the intentional production or feigning of psychological (often psychotic) symptoms suggestive of a mental disorder. Stimulants may be used to induce restlessness or insomnia; hallucinogens, to create altered levels of consciousness; and hypnotics, to produce lethargy. This psychological factitious condition

www.ketabpezeshki.com 66485457-66963820

is less common than factitious disorders with physical symptoms and is almost always superimposed on a severe personality disorder.[2,17]

Physical Symptoms

The intentional production of physical symptoms may take the form of fabricating of symptoms without signs (e.g., feigning abdominal pain), simulation of signs suggesting illness (e.g., fraudulent pyuria, induced anemia), self-inflicted conditions (e.g., the production of abscesses by injection of contaminated material under the skin), or genuine complications from the intentional misuse of medications (e.g., diuretics, hypoglycemic agents).[21] These patients are predominantly unmarried women younger than 40 years. They typically accept their illness with few complaints and are generally well-educated, responsible workers or students with moral attitudes and otherwise conscientious behavior.[21,27,28] Many are in health care occupations, including nurses, aides, and physicians.

These patients are willing to undergo incredible hardship, limb amputation, organ loss, and even death to perpetuate the masquerade.[21] Although multiple hospitalizations often lead to iatrogenic physical conditions, such as postoperative pain syndromes and drug addictions, patients continue to crave hospitalization for its own sake. They typically have a fragile and fragmented self-image and are susceptible to psychotic and even suicidal episodes.[27] Interactions with the health care system and relationships with caregivers provide the needed structure that stabilizes the patient's sense of self. The hospital may be perceived as a refuge, sanctuary, or womblike environment.[4,21,24,29] Some patients are apparently driven by the conviction that they have a real but as yet undiscovered illness. Consequently, artificial symptoms are contrived to convince the physician to continue a search for the elusive disease process.[21] Factitious illness behavior has even emerged on the Internet. "Virtual support groups" offering person-to-person communications through chat rooms and bulletin boards have been perpetrated by individuals, under the pretense of illness or personal crisis, for the purpose of extracting attention or sympathy, acting out anger, or exercising control over others.[30]

There has been increasing recognition of factitious illness produced by children (distinct from the MSBP described later). These children, ranging in age from 8 to 18 years, are typically "bland, flat and indifferent during their extensive medical interventions . . . depressed, socially isolated and often obese."[31] Among the most common presentations are fever without clear etiology, diabetic ketoacidosis, purpura, and recurrent infections. The prognosis is good if identification and psychotherapeutic intervention can be carried out at a young age.[31]

Munchausen Syndrome

The uncommon patient with true Munchausen syndrome has a prolonged pattern of "medical imposture," usually years in duration. The behavior usually begins before the age of 20 years and is diagnosed between the ages of 35 and 39 years. Twice as many men as women are affected.[4,32] Patients' entire adult lives may consist of trying to gain admission to hospitals and then steadfastly resisting discharge. Their career of imposture usually lasts about 9 years but has continued unabated for as long as 50 years.[4] The quest for repeated hospitalizations often takes these patients to numerous and widespread cities, states, and countries.[2]

These individuals see themselves as important people, or at least related to such persons, and their life events are depicted as exceptional.[32] They possess extensive knowledge of medical terminology. There is frequently a history of genuine disease, and the individual may exhibit objective physical findings.[27]

The symptoms presented are "limited only by the person's medical knowledge, sophistication, and imagination."[2] The alleged illnesses involved have been termed *dilemma diagnoses* in that investigators rarely can totally rule out the disorder, clarify the cause, or prove that it did not exist at one time.[4] Common presentations are those that most reliably result in admission to the hospital, such as abdominal pain, self-injection of a foreign substance,[10,11] feculent urine, bleeding disorders, hemoptysis, paroxysmal headaches, seizures, shortness of breath, asthma with respiratory failure,[4,33] chronic pain,[25] acute cardiovascular symptoms (e.g., chest pain, induced hypertension and syncope),[32] renal colic and spurious urolithiasis,[7] fever of unknown origin (hyperpyrexia figmentatica),[5,11] profound hypoglycemia, and coma with anisocoria.[34] Some self-induced conditions are highly injurious or even lethal.[10]

The patient usually presents during evenings or on weekends so as to minimize accessibility to psychiatric consultants, personal physicians, and past medical records.[11,27] In teaching institutions these patients often present in July, shortly after the change in resident house officers.[4] They relate their history in a precise, dramatic, even intriguing fashion, embellished with flourishes of pathologic lying and self-aggrandizement. *Pseudologia fantastica,* or pathologic lying, is a distinctive peculiarity of these patients. In a chronic, often lifelong behavior pattern, the patient typically takes a central and heroic role in these tales, which may function as a way to act out fantasy.[35] The history quickly becomes vague and inconsistent, however, when the patient is questioned in detail about medical contacts.[2,29] Attempts to manage the complaint on an outpatient basis are adamantly resisted.[25] Once admitted, the patient initially appeals to the physician's qualities of nurturance and omnipotence, lavishing praise on the caregivers. Behavior rapidly evolves, however, as the patient creates havoc on the ward by insisting on excessive attention while ignoring both hospital rules and the prescribed therapeutic regimen.[2] When the hoax is uncovered and the patient confronted, fear of rejection abruptly changes into rage against the treating physician, closely followed by departure from the hospital against medical advice.[10,11,25]

Munchausen Syndrome by Proxy

The diagnosis of MSBP depends on specific criteria (Box 114-1).[14] The presenting complaints typically evade definitive diagnosis and are refractory to conventional therapy for no apparent reason.[14] The symptoms are usually more than five in number, presented in a confused picture; they are unusual or serious and, by design, unverifiable. They invariably occur when the mother is alone with the child or otherwise unobserved.[36] In 72 to 95% of cases, simulation or production of illness occurs while the victim is hospitalized.[14]

Simulated illness, faked by the mother without producing direct harm to the child (e.g., the addition of blood to a urine specimen), is present in 25% of cases. *Produced illness,* which the mother

Box 114-1 Criteria for the Diagnosis of Munchausen Syndrome by Proxy

1. Apparent illness or health-related abnormality that the parent or someone who is in loco parentis has concocted or produced
2. Presentation of the child for medical treatment, usually persistently
3. Failure by the perpetrator to acknowledge the true etiology or the deception
4. Cessation of the acute symptoms and signs of illness when the child is separated from the perpetrator

www.ketabpezeshki.com 66485457-66963820

actually inflicts on the child (e.g., the injection of feces into an intravenous line), is found in 50% of cases. Both simulated and produced illnesses are found in 25% of cases.[14]

MSBP most commonly arises with factitious bleeding, seizures, central nervous system (CNS) depression, apnea, diarrhea, vomiting, fever, and rash.[14] Reported techniques of simulation or production of disease include administration of drugs or toxins (e.g., chronic arsenic poisoning, ipecac, warfarin, phenolphthalein, hydrocarbons, salt, imipramine, laxatives, CNS depressants), caustics applied to the skin, and nasal aspiration of cooking oil.[12,14-16,27,37] Techniques of asphyxiation include (1) covering the mouth or nose with one or both hands, a cloth, or plastic film and (2) inserting the fingers into the back of the mouth. In such instances, even struggling infants may sustain no cutaneous markings.[38] Cases involving seizures are common and may involve third-party witnesses. On personal questioning, however, these witnesses frequently deny the occurrence of seizure activity.[14]

In a variant of MSBP termed *serial Munchausen syndrome by proxy,* there may be a history of similar strange presentations in multiple siblings, although typically only one child is involved at a time.[15,16,38] In 9% of such cases there is a history of siblings who died under mysterious circumstances.[14]

Perpetrator Characteristics. Ninety-eight percent of perpetrators are biologic mothers who come from all socioeconomic groups.[14] Many have a background in health professions or social work, features of Munchausen syndrome themselves, or a past history of psychiatric treatment, marital problems, or suicide attempts.[14,15] Depression, anxiety, and somatization are common, but frankly psychotic behavior by the mother is atypical.[14,16] Perpetrators of MSBP have an inherent skill in manipulating health workers and child protection services.[39] They are pleasant, socially adept, cooperative, and appreciative of good medical care. They often display a peculiar eagerness to have invasive procedures performed on their child.[3] They often choose to stay in the hospital with their child, cultivate unusually close relationships with hospital staff, and thrive on the staff's attention.[12-14,16,37] This affable relationship with the medical team rapidly changes to excessive anger and denial when the perpetrator is confronted with suspicions.[19]

Most of these mothers have had an abusive experience early in life, and they use the health care system as a means to satisfy personal nurturing demands.[36,40] They often cannot distinguish their needs from the child's and satisfy their own needs first. They derive a sense of purpose from the medical and nursing attention gained when their children are in the hospital.[13,14,16,40] Alternatively, the behavior may enable the mothers to escape from their own physical or psychological illnesses, marital difficulties, or social problems.[36]

Victim Characteristics. Victims of MSBP are equally male and female children. The mean age at diagnosis is 40 months, and the mean duration from the onset of signs and symptoms to diagnosis is 15 months.[14] A known physical illness that explains part of the symptoms is common among these children.[40] Most have a history of significant failure to thrive and have been hospitalized in more than one institution. Delays in many areas of performance and learning, difficulty with family relationships, attention deficit disorder, or clinical depression may coexist.[16] Some of these victims may have factitious disorder later in life.[3] Victims of MSBP are also found among the elderly population, although this is uncommon.[41]

Malingering

Malingering is frequently found in association with *antisocial personality disorder*. On questioning, malingerers are vague about prior hospitalizations or treatments. The physicians who previously treated them are usually unavailable. At times, malingerers may be careless about their symptoms and abandon them when they believe no one is watching.[27] In some "patients," such as those seeking drugs, homeless persons seeking hospital admission on a cold night, or prisoners wanting a holiday from incarceration, the secondary gain may be clear. In other persons, the external incentive may be obscure.

In contrast to the person with factitious disorders, the malingerer prefers *counterfeit mental illness* because it is objectively difficult to verify or to disprove. Amnesia is the most common psychological presentation, followed by paranoia, morbid depression, suicidal ideation, and psychosis.[20]

DIAGNOSTIC STRATEGIES

Factitious Disorders

Initial diagnosis is often delayed because the possibility of factitious disease is not considered, physicians may be unfamiliar with this problem, or the patient does not exhibit the type of personality expected with this behavior.[7] Diagnosis may be confounded by genuine medical illnesses predating and coexisting with a factitious disorder. For example, patients with factitious hypoglycemia may have a history of insulin-dependent diabetes mellitus, or factitious skin disorders may be preceded by true dermatologic diseases.[1] Identification of a factitious disorder is usually made in one of four ways: (1) the patient is accidentally discovered in the act, (2) incriminating items are found, (3) laboratory values suggest nonorganic etiology, or (4) the diagnosis is made by exclusion.[17] Wallach[42] provides a useful review of the laboratory diagnosis of factitious disorders, including feigned endocrine, hematologic, genitourinary, gastrointestinal, and infectious disorders.

Suspected MSBP requires a detailed description of the event or illness and a search for caregiver witnesses, who should be interviewed personally. Although it is essential to see the child when the symptoms are present, the parents show great ingenuity at frustrating this effort.[40] Additional history of unusual illness in siblings and parents should be sought. Child victims who are verbal should be interviewed in private about foods, medicines, and their recollection of the symptoms or events. Prior medical records of the victim and, if possible, the siblings should be examined, although parents may impede such data gathering.

The major obstacle to early discovery of MSBP is its omission from the differential diagnosis. When it is considered, the diagnosis is generally made easily and quickly.[14] A suspected diagnosis may be confirmed through separation of the parent from the child (with consequent cessation of symptoms), covert video surveillance during hospitalization, or toxin screens.[16,36,38] In the majority of cases, the caregiver attempts to induce episodes surreptitiously while in the hospital, often during the first day of admission.[14,36]

Malingering

Malingering should be strongly suspected with any combination of certain factors (Box 114-2).[2,43] A definitive diagnosis of malingering is rare and can be established only with the patient's

Box 114-2 Characteristics of Malingering

1. Medicolegal context of the presentation (e.g., the patient was referred by his or her attorney)
2. Marked discrepancy between the person's claimed stress or disability and objective findings
3. Poor cooperation during the diagnostic evaluation or poor compliance with previously prescribed treatment regimens
4. The person exhibits or has a history of antisocial behavior

www.ketabpezeshki.com 66485457-66963820

confession.[44] Because malingering constitutes criminal behavior, documentation of this diagnosis should be made with care.[20] In the absence of proof of wrongdoing, it is best to assume that the patient is not a malingerer but rather a common somatizer.[44] Malingerers who pursue drugs may report an unusually large number of drug allergies to persuade the physician to prescribe their drug of choice or simply insist on a specific drug (e.g., meperidine [Demerol] or hydromorphone [Dilaudid]).[45] Unfortunately, the Internet offers a wide availability of quality medical advice on how to convincingly feign pain and disability.[45]

DIFFERENTIAL CONSIDERATIONS

Patients with factitious disorders are distinguished from malingerers because their desired hospitalization or surgery seems to offer no secondary gain other than to play the sick role.[2,10,22] The clinical presentation of the majority of patients with factitious disorders, unlike those with Munchausen syndrome, is relatively subtle and convincing. The complaints are generally chronic in nature rather than emergent and precipitous, and there are no obvious associated behavioral aberrations.[21] The most important diagnosis to be excluded with a likely factitious disorder is a genuine medical condition that might account for the illness. The chronicity of malingering is usually less than that associated with factitious disorder, and malingerers are more reluctant to accept expensive, possibly painful, or dangerous tests or surgery.[22]

MANAGEMENT

Factitious Disorders

Treatment options for factitious disorders depend on the patient's characteristics. Although it is challenging, management of common forms of factitious disorder can be more rewarding, especially with adolescents, than management of Munchausen syndrome.[1,9,24,29] The prognosis is more favorable for cases with an underlying depression than for those associated with borderline personalities.[27]

The best approach to patients with factitious disorder, other than Munchausen syndrome and MSBP, is controversial. Direct nonaccusatory confrontation has been advocated as "the foundation of effective management" when it is coupled with the assurance that an ongoing relationship with a physician will be provided.[4,21,22,27] This may be the first step in the acceptance of outpatient therapy.[4]

Others point out that confrontation is ineffective in most patients and may even be counterproductive in that it threatens to undermine a needed psychological defense. Enforced recognition of external objective reality, while simultaneously disallowing the patient's subjective experience, may generate even more dysfunction directed at legitimizing and maintaining symptoms and may even place the patient at risk for suicide.[9,17,29,46,47] Some patients may relinquish this defense if they feel safe in doing so and may abandon a claim to disease if some face-saving option is offered. This approach, termed the *therapeutic double bind* or *contingency management,* involves informing the patient that a factitious disorder may exist. The patient is further told that failure to respond fully to medical care would constitute conclusive evidence that the patient's problem is not organic but rather psychiatric. The problem is therefore reframed or redefined in such a way that (1) symptoms and their resolution are both legitimized and (2) the patient has little choice but to accept and respond to a proposed course of action or seek care elsewhere.[9,47]

Individuals with Munchausen syndrome typically demonstrate overt sociopathic traits or a borderline personality disorder and are demanding and manipulative, especially regarding analgesics.[5,9] They have been described as "essentially untreatable," and successful management of this condition is, in fact, considered reportable. Early confrontation or limit setting, especially regarding drug use, is advocated.[9,11,21,25,27] Although Munchausen patients typically do not want to be examined extensively, a thorough physical examination should be performed to rule out physical disease.

MSBP constitutes a form of child (or elder) abuse, and appropriate action to protect the victim, including notification of state social service agencies, should take immediate priority.[38,41] If available, a pediatrician who has expertise in child abuse should assess the case. When the diagnosis has been established and the parents have been confronted, psychiatric care should be made immediately available to the parents because maternal suicide is a significant risk.[14]

Malingering

Malingerers do not want to be treated. Because they are "gaming the system" for personal advantage, the last thing they want is an accurate identification of their behavior and appropriate intervention. The emergency physician should maintain clinical neutrality, offering the reassurance that the symptoms and examination are not consistent with any serious disease.

Some authors have characterized patients' use of medical resources under false pretenses as criminal behavior, and several states have enacted legislation against the fraudulent acquisition of medical services with successful prosecution of such behavior.[48] Conversely, patients with factitious disorders can and do sue. In dealing with such patients, it is advisable to involve hospital administration and risk management. Clandestine searches are inadvisable, and respect for the patient's confidentiality should be maintained.[17]

DISPOSITION

Patients suspected of having a factitious disorder should be referred for primary care follow-up, and if it is acceptable to the patient, psychiatric referral should also be arranged. Referral to other medical specialists or hospitalization should be avoided when possible.

The manner of presentation and the unavailability of past medical history often allow patients with Munchausen syndrome to achieve hospital admission. If the patient is discharged from the emergency department, outpatient primary care follow-up and psychiatric referral should be offered, although both are likely to be refused.[25]

Because perpetrators of MSBP typically induce symptomatic episodes soon after hospitalization, admission of the victims (children or elderly persons) without taking appropriate precautions may actually place them at increased risk.[14] Visits by the suspected perpetrator should be closely supervised, and no food, drink, or medicines should be brought in by the family. Protective services should be notified. Out-of-home placement of children in established cases of MSBP is advisable, and best outcomes are seen among children taken into long-term care at an early age without access to their mother. Children allowed to return home have a high rate of repeated abuse.[39] In 20% of reported deaths, the parents had been confronted and the child sent home to them, subsequently to die.[14]

After courteous but assertive reassurance, suspected malingerers should be offered primary care follow-up if the symptoms do not resolve. These individuals may become threatening when they are either denied treatment or overtly confronted.[19]

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- Emergency department patients who have consciously synthesized symptoms and signs may be divided into two broad diagnostic categories: (1) those with obvious secondary gain (malingering), who control their actions, and (2) those with a motivation of achieving the sick role (factitious disorders), who cannot control their actions.
- Emergency department management of patients suspected of fabricating disease includes a caring attitude and a search for objective clinical evidence of treatable medical or psychiatric illness.
- Unnecessary tests, medications, and hospitalizations should be avoided in the absence of objective evidence of a medical or psychiatric disease, and patients should be referred for ongoing primary care.
- In cases of suspected MSBP involving children or elderly persons, protection of the victim takes first priority.

Chapter 115

Suicide

Stephen A. Colucciello

PERSPECTIVE

Although suicide has occurred in all societies since the beginning of recorded history, attitudes toward suicide have differed dramatically among various eras and cultures. Seneca viewed suicide as the ultimate expression of personal freedom, but later Judeo-Christian religions have routinely condemned it. Shakespeare portrayed suicide sympathetically and expressed either pity or admiration for the victim.[1]

In the United States, suicide is illegal in 49 states, and only since 1994 has assisted suicide of terminally ill patients been sanctioned in Oregon. On the Internet, suicide help groups provide active advice on methods, and numerous bulletin boards condemn them. More than 100,000 sites about suicide now appear on the Internet.[2]

Suicidal patients represent almost 2% of emergency department (ED) visits.[3] Two facts are especially important to remember in approaching potentially suicidal patients. First, many suicide attempts occur during an acute crisis, such as a personal loss or the exacerbation of an underlying psychiatric disorder. This acute crisis is usually time limited and may be resolvable or treatable. Second, except for the acutely psychotic patient, suicidal patients are usually ambivalent about dying. The attitude and approach of the emergency physician can help a patient choose crisis resolution rather than death.

Definitions

The term *suicide,* from the Latin *suicidum* ("to kill the self"), refers to a continuum of thought and action that runs from ideation to completion of the act.[4] *Parasuicide* is used by the British to describe an attempted suicide that is more of a gesture than a serious act. Statistically, there are 10 to 40 suicide attempts for every completed act.[5] *Chronic suicidal behavior* consists of recurrent self-destructive acts, such as heavy drinking in the presence of alcoholic liver disease. *Occult suicide* refers to self-destructive acts disguised as accidents, such as the intoxicated, depressed driver in an apparently accidental car crash. *Silent suicide* describes the act of slowly killing oneself by nonviolent means, such as starvation or noncompliance with essential medical treatment. Silent suicide is most common in elders and frequently goes unrecognized.

A *suicide pact* is an agreement between two people who are intimately involved and accounts for 0.6% of all suicides.[6] *Mass suicide* or *group suicide* involves a number of willing and sometimes not-so-willing persons, such as members of an apocalyptic cult.

Epidemiology

Suicidal ideation is common, and as many as one in three people consider suicide during their lifetime.[7] In 2006, suicide was the eleventh leading cause of death among persons older than 9 years, accounting for 33,289 deaths.[8] This is the equivalent of 89 suicides per day or one suicide every 15 minutes. It is the fourth leading cause of death for adults between the ages of 18 and 65 years. In the United States, there are more than 800,000 suicide attempts per year, many of which do not present to EDs.[9]

In one study performed during a 5-year period, there were approximately 412,000 annual ED visits for attempted suicide and self-inflicted injury. The most common method of injury was poisoning (68%), followed by cutting or piercing (20%). One third were admitted to the hospital, with 31% going to the intensive care unit. A psychiatric diagnosis was assigned for 55% of visits, with depressive disorder accounting for 34% and alcohol abuse for 16%.[10]

The rate of self-harm visits to the ED appears to be increasing. From 1999 to 2004, intentional self-harm episodes increased by 20% with a correspondingly greater increase in hospitalizations for the same.[11] Unemployment and financial troubles may play a role in this rise, and a recent study links suicidal behavior to economic conditions. Longitudinal data show that overall suicide rates rise during recessions and fall during expansions, particularly for patients aged 25 to 64 years.[12] In addition to the recent economic troubles, there are other factors that may play a role in the increasing number of suicide attempters seen in the ED. These include a rise in homelessness and the collapse of the mental health hospital system in most states.[13]

Suicide rates vary with age, gender, race, and marital status. Suicides are highest among older individuals, particularly elderly white men. The case fatality rate also increases tremendously with advancing age, from 5% in youths aged 5 to 14 years to 34% in adults older than 64 years.[14] White men commit 73% of all suicides in the United States. Whites and Native Americans are much more likely to commit suicide than are African Americans, Hispanics, or Asians. Marriage decreases the likelihood of suicide, but the rate of suicide is higher for separated or divorced people than for those who never had a close relationship.

Women attempt suicide three to four times more often than men do, whereas men are three to four times more likely to succeed. In one U.S. study, only 5% of suicide attempts by women were fatal compared with 23% of those by men.[14] In general, men tend to use more lethal methods, such as firearms. Worldwide, Chinese and Indian women have rates of suicide higher than those of women of other nationalities.[15] Pregnant women are at a

Lack of religious affiliation

Emotional Factors
Hopelessness
Chronic loneliness
Fixation on death

significantly lower risk than are women of childbearing age who are not pregnant. Motherhood seems to protect against suicide, except that postpartum depression is associated with a higher than normal suicide rate.

Most people who attempt suicide have one or more known risk factors (Box 115-1). Individuals with the highest risk include those with psychiatric disorders, alcohol or substance abusers, adolescents, elders, and patients with certain chronic illnesses. In patients hospitalized for psychiatric disorders, the first month after discharge carries a high risk of suicide,[16] and that risk is especially great for patients who are in the first week after discharge from a psychiatric facility.[17] Any prior history of suicide, even in the remote past, is an important risk factor.[18]

A strong association may exist between suicide risk and bisexuality or homosexuality in men.[19] This association is also seen in lesbian, gay, and bisexual adolescents.[20] Unemployment appears to be a risk factor for suicide among 18- to 24-year-old men.[21] Homeless people with mental illness are at particularly high risk for suicidal behavior, in part because of the high prevalence of traditional risk factors. Recent incarceration is also a risk factor for suicide. During the first 2 weeks after release, the risk of death among former inmates is more than 12 times that of the general population. The leading causes of death among former inmates include drug overdose, cardiovascular disease, homicide, and suicide.[22] In general, the risk of suicide in recently released prisoners approaches that in recently discharged psychiatric patients.[23]

Suicide completers and suicide attempters represent separate but overlapping populations.[24] Although 10 to 15% of suicide attempters ultimately complete suicide, 60 to 70% of suicide completers have no prior history of attempts and commit suicide on the first known attempt.[25] In individuals who committed suicide while not in contact with mental health services, nearly one third of cases had no concurrent mental disorder.[26]

PATHOPHYSIOLOGY AND ETIOLOGY

Societal, Psychiatric, and Biologic Factors

There are many motivations to attempt suicide. It may be seen as the only escape from a terminal disease or intense chronic pain. It may be an act of revenge or political protest. Most suicide attempts occur in individuals with intense feelings of hopelessness, guilt, or self-hatred, often compounded by the exacerbation of an underlying psychiatric disorder or by the occurrence or perception of a great personal loss. The underlying causes of suicide are similar for adults and adolescents; however, adolescents tend to romanticize suicide, and "copycat" suicides are frequent after the suicide of celebrities or friends. Regardless of the motivation, most suicide attempters are ambivalent, and their attraction to death is usually counterbalanced by a desire to live. This internal conflict is reflected in the high ratio of attempted to completed suicides and by the fact that most people consult a physician shortly before their death.

Psychoanalysts explain suicide in terms of psychic forces. Freud believed that suicide stems from aggression initially directed toward another person but that ultimately turns against the self. Depression and suicide in the Freudian model represent internalized anger. Many authorities have recognized this association between aggression and suicide. In the United States, more than 1000 deaths each year result from murder-suicides. The perpetrators are usually depressed mothers, despairing elderly men, or young men with intense sexual jealousy. Their victims are usually young children, blood relatives, or female sexual partners. The dual risk for suicide and violence is greatest in alcoholics.[27]

The impulses that lead to suicide differ between violent and nonviolent people. "Suicidality" is correlated with anger, fear, and suspiciousness in violent individuals and with feelings of sadness and despair in nonviolent persons. The psychic roots of suicide may arise from childhood trauma. Chronic loneliness during childhood is associated with subsequent suicide attempts during adolescence, and a history of sexual molestation is linked to suicide attempts in women and adolescents.

Current research suggests a biologic basis for depression and suicide involving the serotonergic and dopaminergic systems. People who attempt suicide have altered serotonin receptor function and low serotonin levels.[28,29] These abnormalities may be regulated through serotonergic-related genes in persons with major depression.[30] The genetic basis of suicide is not clearly understood. The STin2 genetic locus might, at least in part, account for the observed familial aggregation of suicidal behavior.[31] Polymorphisms in the tryptophan hydroxylase gene may affect the synthesis of serotonin. Recent data also indicate that certain genetic markers may be linked to suicidal ideation associated with medications used to treat depression.[32] The genetic susceptibility to suicide, however, may affect individuals only when it is associated with psychiatric illness or stress.[33] The rate of suicide is twice as high in families of suicide victims, and a family history

www.ketabpezeshki.com 66485457-66963820

of suicide predicts suicide independent of severe mental disorder.[34] Relatives of suicide completers are more than 10 times more likely than relatives of comparison subjects to attempt or to complete suicide.[35]

Depressed patients who attempt suicide excrete less homovanillic acid in their urine and produce less dopamine than depressed patients who have not attempted suicide. Low concentrations of dopamine and serotonin metabolites in the cerebrospinal fluid also correlate with suicidal behavior. Suicide attempts in women vary with estrogen levels, with 42% of attempts occurring during the first week of the menstrual cycle.[36]

Neuroanatomy may also influence suicidality; suicide victims have smaller right-sided parahippocampi than control subjects.[37] Although there are no currently available laboratory tests that can identify individuals at increased risk for suicide, research holds promise for biologic markers in the future.

Some drugs, including reserpine, benzodiazepines, and barbiturates, are associated with depression and suicidal behavior. The Food and Drug Administration recently linked suicidal ideation among children and adolescents to selective serotonin reuptake inhibitors (SSRIs) and added a black box warning for SSRI use in all age groups.[38] It is ironic that in both the United States and the Netherlands, SSRI prescriptions for children and adolescents decreased after these regulatory warnings and these decreases were associated with *increases* in suicide rates in both children and adolescents.[39] Patients who commit suicide shortly after the initiation of antidepressant medications are explained by the "mobilization of energy" theory.[40,41] According to this theory, patients who are profoundly depressed may have the energy to attempt suicide only as their condition improves with treatment. Such patients should be monitored very closely during their initial phase of treatment.

Methods of Attempting Suicide

Most completed suicides involve firearms (70%), whereas most attempted suicides involve the ingestion of drugs or poisons (72%).[42] In one large study, poisoning with drugs accounted for 74% of acts but only 14% of fatalities; firearms and hanging accounted for only 10% of acts but 67% of fatalities. Firearms were the most lethal means (91% resulted in death), followed by drowning (84%) and hanging (82%).[14] Episodes involving firearms are 2.6 times more lethal than the second most lethal suicide method, suffocation.[43] In 2005, 17,002 suicides involved firearms in the United States.[44] Guns represent the most common method of suicide in all victim subgroups, especially among older persons and adolescents, and the use of guns has increased dramatically in the past decade, recently replacing ingestion as the major cause of suicide among women.[45] The simple presence of a gun in the home represents an independent risk factor for firearm-related suicide but not by non-firearm means.[46] This is particularly true for adolescents, whose risk for suicide increases 5 to 10 times when there is a gun in the household.[47,48] In general, firearm prevalence is positively related to the suicide rate, even after control for rates of attempted suicide.[49] Suicide by handgun is often associated with drug or alcohol use.[50] The rate of gun-related suicide is 57 times higher in the first week after purchasing of a handgun.[51]

After gun-related deaths, other lethal methods chosen by men include hanging, suffocation, and jumping from a height, whereas women are more likely to commit suicide by poisoning. Antidepressant overdose is the most common cause of suicide by ingestion.[52] Cyclic antidepressants are associated with more deaths because of their widespread use and high potential for lethality. Most patients hospitalized for self-poisoning have ingested drugs prescribed by their physicians for depression.[53] SSRIs, including fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil), are less lethal when they are taken in overdose and have replaced cyclic antidepressants as the first therapy in depression.

The method of suicide depends on many factors, including psychic issues of self-hate, the desire for a peaceful versus violent death, and the availability of fatal means. Those who jump to their death are more likely to be single, unemployed, or psychotic. Those who use firearms are more likely to be male, to be alcoholic, to have been arrested, or to have an antisocial or borderline personality disorder.[54] Communities with tall buildings and bridges have higher rates of suicide from falls, whereas suicide by gunfire occurs more often in areas where firearms are prevalent.

"Suicide by cop" occurs when a suicidal individual intentionally provokes a police officer by orchestrating a lethal situation in which the officer is forced to shoot in self-defense or to protect other civilians. This may account for as many as 11% of officer-involved shootings in Los Angeles.[55] Certain individuals carry a suicide note; some offer an eerie postmortem apology to the police officer who ultimately kills them.

CLINICAL FEATURES

Psychiatric Illness

Although most psychiatric patients never attempt suicide, most people who commit suicide have either a diagnosable psychiatric illness or alcoholism. Exceptions include those with mental retardation, dementia, and agoraphobia.[56] Patients with an affective disorder, especially major depression, are at highest risk.[57,58] Approximately 15 to 20% of people with major depression commit suicide, usually while under psychiatric care.[59] Individuals who experience hopelessness, anhedonia (loss of ability to experience pleasure), and mood cycling are at highest risk. Impulsive-aggressive personality disorders and alcohol abuse are independent predictors of suicide in major depression.[60]

Approximately 10% of schizophrenic patients will kill themselves. Psychotic patients who commit suicide are most often unmarried white individuals with high intelligence quotient scores.[61] Patients with borderline personality disorders are also predisposed to commit suicide. Women with borderline personality disorder who attempt suicide often have a history of childhood sexual abuse and impulsive behavior. The risk is especially high when patients require hospitalization for psychiatric illness and is greatest the first month after discharge.[62,63]

Approximately 40% of patients with panic disorder attempt suicide at some point in their lives. These patients usually have an additional comorbid psychiatric diagnosis (e.g., borderline personality disorder, substance abuse, emotional instability). However, any preexisting anxiety disorder (including social phobia, simple phobia, generalized anxiety disorder, panic disorder, agoraphobia, obsessive-compulsive disorder) is an independent risk factor for subsequent suicidal ideation and attempts.[64] Post-traumatic stress disorder, sustained by military combat personnel and disaster survivors, is also associated with suicide. Post-traumatic stress disorder frequently coexists with a major depressive episode, and this combined psychopathology enhances the risk for suicidal behavior.[65] In 2005, there were at least 6256 suicides among those who served in the U.S. armed forces, a rate double that of nonveterans. Veterans between the ages of 20 and 24 years who served in Iraq or Afghanistan had the highest suicide rate among all veterans.[66]

Alcoholism and Substance Abuse

Of successful suicides reported by the National Violent Death Reporting System, 33.3% tested positive for alcohol, 16.4% for opiates, 9.4% for cocaine, 7.7% for marijuana, and 3.9% for amphetamines.[67] Other studies show that approximately 25% of all suicides involve alcoholics, and estimates of the lifetime risk

www.ketabpezeshki.com 66485457-66963820

of suicide from chronic alcoholism range from 3 to 25%.[68] Alcoholics who commit suicide usually have multiple risk factors, including major depressive episodes, unemployment, medical illness, and interpersonal loss. In psychiatric patients, the use of alcohol increases depression and suicidal behavior.

Substance abuse among mentally ill patients is increasingly common. Psychoactive substance abuse is associated with a greater frequency, repetitiveness, and lethality in suicide attempts than other medications are.

Nearly half of all adolescents who attempt suicide use drugs shortly before the attempt, and alcohol intoxication is strongly associated with suicide by firearms.[69] Cocaine use is particularly dangerous. In New York City, 20% of all suicide victims younger than 61 years used cocaine within days of their death. Among young Hispanic men, nearly half of the suicide victims have toxicologic screens positive for cocaine.[70] In general, cocaine abusers choose violent means of self-destruction, especially firearms.

Adolescents

Suicide among adolescents has quadrupled during the past 40 years and is now the third leading cause of death (after accidents and homicides) in people between 5 and 24 years of age.[71] Approximately 2 million U.S. adolescents attempt suicide each year, and 19% report serious consideration of suicide in the past year.[72] Although some authorities believe that the rise in adolescent suicide simply corresponds to changing demographics in the United States, others believe that the increase is related to a growing sense of hopelessness, increased economic pressures, and access to firearms. In a survey of high-school students in North Carolina, 24% had seriously considered suicide, 19% had planned suicide, and 9% had actually attempted suicide during a 1-year period.[73]

Adolescent girls are more likely to attempt suicide, whereas adolescent boys are more likely to complete suicide; the ratio of attempted to completed suicides is 25:1 for adolescent girls and 3:1 for boys.[74] Most adolescents who complete suicide have made previous suicide threats.

The majority of youths who kill themselves meet criteria for diagnosable psychiatric disorders, and both alcohol and substance abuse play a significant role in teenage suicide attempts. Adolescents with panic attacks are twice as likely as adolescents without panic attacks to make suicide attempts.[75] Gay, lesbian, bisexual, or “not sure” youths may also be more prone to self-harm.[76] Belonging to the “Goth” subculture is a predictor of self-harm and attempted suicide.[77]

Nearly 40% of youths in runaway programs report prior suicide attempts.[78] Young people may also be influenced by movies or television shows that feature suicide. Teenage suicides typically increase after television broadcasts on the subject.

From 1989 to 1995, suicide by firearm in young people increased dramatically.[79] The firearm-related suicide rate in U.S. adolescents is 11 times higher than the combined rates of 25 other industrialized countries.[80] Having a gun in the home places the troubled adolescent in great danger, and storing the gun in a locked cabinet or separating it from the ammunition does not deter suicide attempts.[81] Surprisingly, up to 23% of adolescents who have attempted suicide report that their families continue to keep firearms and ammunition in the home despite their suicide attempt.

Older Adults

The highest rates of completed suicide occur in elders. Suicide by firearm is the fourth leading cause of injury-related deaths among older U.S. residents.[82] Older Americans use highly lethal methods when attempting suicide and, unlike adolescents, rarely stage an attempt that permits rescue. Self-inflicted gunshot wounds account for 88% of elder suicides.

White men older than 65 years account for approximately 80% of suicide deaths, whereas suicide is rare among elderly people belonging to minority groups.[83] Suicide among older adults is especially common in those with prior suicide attempts or major depression. Severity of depression is the strongest predictor of suicide in elders.[84] Physicians often overlook signs of depression in older patients, even though most who commit suicide see their primary care physician during the month before their death. In one study, almost half of all elders who committed suicide visited a physician in the preceding week.[85] Elders also have more chronic illnesses that predispose to suicide. Perceived poor health, poor sleep quality, and limited presence of a relative or friend to confide in are also associated with suicide among elders.[86]

Chronic Illness

Patients with terminal illnesses may commit suicide to end their suffering and to reduce the emotional and financial burden on their families. Diseases more highly associated with suicide include cancer, stroke, renal failure, congestive heart failure, and chronic lung disease. In elders, cancer, congestive heart failure, chronic obstructive lung disease, seizure disorder, urinary incontinence, anxiety disorders, depression, bipolar disorder, and moderate to severe pain are specific illnesses associated with suicide.[83]

The acquired immunodeficiency syndrome (AIDS) epidemic has also increased suicide rates, and the relative risk of suicide in men with AIDS is nearly 37 times higher than that in uninfected men. Patients who are positive for human immunodeficiency virus but do not have AIDS-defining conditions are more likely to be suicidal than those with active disease.[87]

History

Recognition of Depression and Suicide Potential

Recognition of suicide potential is relatively straightforward in patients who present shortly after a suicide attempt as well as in individuals who complain of depression or express suicidal ideation during their evaluation. The potential for suicide should also be considered in patients with any acute problem related to chronic alcoholism, substance abuse, or any psychiatric disorder. Silent suicide is possible with patients who present to the ED repeatedly because of noncompliance with treatment of their medical disorders. Occult suicide should be suspected in patients who “unintentionally” overdose or have had “accidental” gunshot wounds, lacerated wrists, automobile crashes, or falls from heights.

Patients Who Present after a Suicide Attempt or Have Suicidal Ideation

After a suicide attempt, patients with a normal mental status should be asked about the details of the act after medical evaluation and treatment are initiated. Suicidal patients may give inaccurate histories or may refuse to speak to the physician. Because most people who attempt suicide communicate their intent to others at some point, family, friends, police, and paramedics should be interviewed about the patient’s recent actions and possible motivations. They may also provide information about the specifics of the current suicide attempt. Although some physicians worry that current federal laws regarding patient privacy conflict with the need to obtain information with the family, there is an emergency exception in the Health Insurance Portability and Privacy Act. Section 164.512(j), “Uses and Disclosures to Avert a Serious Threat to Health or Safety,” allows physicians to disclose protected health information without individual authorization

www.ketabpezeshki.com 66485457-66963820

"based on a reasonable belief that use or disclosure of the protected health information was necessary to prevent or lessen a serious and imminent threat to health or safety of an individual or of the public."[88]

Once the patient is medically stable, the presence of risk factors for suicide should be determined. Such factors may include a history of previous suicide attempts or psychiatric care; a history of excessive alcohol or drug use, both acute and long term; family history of suicide; and signs of depression, including a sense of hopelessness. A history of a "near-lethal" prior attempt is particularly worrisome.[89] Patients who have a history of deliberate self-harm (self-poisoning, cutting, burning, or hitting oneself) have a higher risk of suicide, especially male patients.[90] More than 5% of people seen at a hospital after self-harm successfully commit suicide within 9 years.[91]

The patient's marital status and social support are important factors, and the motivation for and the seriousness of the suicide attempt are assessed. Some physicians ask patients to provide their own lists of "reasons why they want to live"—a sort of reverse score for suicidality. If discharge is being considered, patients should be asked whether they would harm themselves if they were released from the ED. Additional demographic information may be helpful (see Box 115-1). The SAD PERSONS mnemonic can be used to document salient points and to facilitate subsequent communications with primary care providers and psychiatrists (Table 115-1).

Patients Suspected of Occult or Silent Suicide Attempts

Patients who are not overtly depressed or suicidal but who exhibit one or more of the high-risk presentations previously described should be assessed in a sympathetic but direct manner in a "graduated" approach. Rapport should first be established during a general medical and psychiatric history, with an evaluation of the patient's home, work, and social situation, followed by specific questions about the signs and symptoms of depression. The physician should ask direct questions about suicide; for example:

Have you ever had the thought that life is not worth living?
Do you have thoughts of killing yourself now?
What plans, if any, have you made to do this?

Patients who are not depressed or suicidal are generally not offended by this approach, and it does not place the concept of suicide into the mind of someone who has not been considering it. Patients who are depressed or suicidal are often thankful and relieved for the intervention.

Physical Examination

Patients should be examined closely for evidence of drug ingestion, trauma, or an associated medical illness. Look at the wrists for evidence of prior cutting attempts. The patient's mental status, vital signs, pupils, skin, and nervous system are helpful in detecting organic conditions, particularly the toxidromes associated with common ingestions. Altered mental status should be assessed to determine whether the condition is caused by an organic (medical) or functional (psychiatric) cause (Table 115-2). Physical findings associated with chronic disease, alcoholism, and substance abuse should be sought. The physical examination is often overlooked or performed in a cursory manner in patients with psychiatric complaints. Up to 50% of patients with an acute psychiatric presentation harbor unrecognized medical illnesses.[92] Patients with evidence of psychosis or auditory hallucinations are at increased risk for suicide, especially those with "command" hallucinations that tell the patients to kill themselves.

DIAGNOSTIC STRATEGIES

Routine toxicologic screening tests are unnecessary in the evaluation of suicidal patients. Nearly all patients with dangerous overdoses and poisonings demonstrate clinical signs within several hours of ingestion. Patients with a suspected overdose may require such testing as an acetaminophen level, electrolyte value determinations, or electrocardiography. Patients with acute depression, particularly if they are newly diagnosed, may need screening tests for underlying medical disorders; however, a primary care physician or psychiatrist can safely perform this evaluation during follow-up.

MANAGEMENT

Out-of-Hospital Care

Out-of-hospital management should focus on the patient's injuries and potential harm from poisoning or overdose. If the patient refuses to be transported to the hospital or becomes aggressive, emergency medical personnel should involve law enforcement officers. All states give police the right to place individuals into protective custody if they are suspected of being a danger to self or others. The presence of law enforcement officers, or even the threat of calling the police for assistance, usually ensures the patient's cooperation during transport. In hospitalized psychiatric

patients, transportation to the medical facility by police is an independent risk factor for an imminent suicide attempt.[93]

Emergency Department

The clinical assessment of suicide potential requires an empathetic approach. Patients feel more comfortable discussing personal issues when health care personnel are friendly, nonjudgmental, and supportive. Unfortunately, ED staff may be unsympathetic toward patients who attempt suicide because of religious or philosophic beliefs, lack of formal psychiatric training, or inadequate time and personnel to provide appropriate psychiatric evaluation. They may perceive the patient's behavior as abusive or manipulative and may become frustrated with ineffective disposition and follow-up options. Failure to anticipate and to overcome these factors can result in inadequate patient assessment and reinforce these patients' already low self-esteem.

The central goal of suicidal screening is to determine the need for acute psychiatric consultation in the ED or the need to transfer or to admit the patient to a psychiatric facility. Only the low-risk patient should be discharged home without psychiatric evaluation. Whereas some EDs provide on-site psychiatric counseling, there is no evidence that brief therapy can prevent suicide or lower risk.[94]

With the recent collapse of state-wide mental health systems, EDs are treating an increasing number of patients with psychiatric complaints, including depression and suicidal ideation. To assist with this growing burden, many EDs are hiring psychiatric nurses to help in the evaluation and treatment of these patients. Some hospitals provide mental health professionals on-call to the ED to screen patients and to provide disposition and commitment recommendations to the ED physicians.

Medical Clearance

The first priority in managing patients is medical stabilization and treatment of injuries, poisoning, or overdose. The second priority is the identification and treatment of associated medical conditions that may underlie a patient's altered mental status or violent behavior. Patients with significant injury, poisoning, or other medical problems should be hospitalized, sometimes in an intensive care setting, where their medical problems can be treated as they remain under constant observation. Five to 40 inpatients commit suicide for every 100,000 hospitalizations.[95,96]

Suicide Precautions

Suicide of a person in a treatment setting is presently the second most frequently reported type of sentinel event.[97] The ED should ensure the patient's safety and prevent further attempts in the department.

Suicidal patients who are calm and cooperative should be placed in an area where they can be safely observed by staff. Having a dedicated "sitter" to watch the patient is helpful and decreases the need for restraints. The sitter should accompany the patient in leaving the area to use the restroom or to smoke. No potentially suicidal patient should be allowed to leave the ED before an evaluation is completed. The use of family members as sitters is discouraged because they may collude with the suicidal patient to leave or may not intervene if the patient attempts to leave. The use of "wander alert" bracelets, which set off an alarm if a patient wearing one crosses an established threshold, may help in monitoring.

Security personnel should search all potentially suicidal patients early in the ED stay, ideally as soon as the complaint of suicide attempt or suicidal ideation is known. Having the patient change into a hospital gown facilitates removal of weapons, medications, and other possessions that might be used to inflict injury, such as belts, neckties, and long shoelaces. The patient's room should be cleared of all potentially harmful objects, including medications, instruments, and glass objects.

Some EDs have a "secure room" designed and stocked to avoid self-harm. These rooms may contain a lockable "pull-down" wall, like those used on storefronts at night, that cover medical equipment and cabinets when a psychiatric patient is in the room. Suture carts, which may contain scissors, scalpels, or other dangerous objects, should also be kept out of reach.

Use of Restraints

Mechanical and chemical restraint use is based primarily on the physician's judgment of the immediate risk of elopement or subsequent suicide attempt as well as personnel available to contain the patient. Some authorities believe that placement of a depressed patient in mechanical restraints can impair rapport and contribute to the patient's diminished self-esteem. Chemical restraints may calm a violent patient but may make subsequent psychiatric evaluation more difficult in the short term.

Nevertheless, restraints may be essential and even lifesaving for uncooperative, violent, or psychotic patients and for those at high risk for elopement or self-harm. The Joint Commission and state and federal governments have stringent requirements for the use of restraints. A hospital policy that conforms to these guidelines and an approved and consistently used restraint flow sheet are important to comply with these regulations. A timed and dated physician order and frequent rechecks of distal neurovascular function are required for all patients placed in restraints. A restraint flow sheet is essential for documentation.

Determination of Risk

Once a patient has demonstrated suicidal behavior or ideation, the physician should determine whether the risk is imminent (i.e., within 48 hours), short term (i.e., within days to weeks), or long term.[7] The likelihood of an impending repeated attempt will drive disposition: psychiatric hospitalization, emergency psychiatric consultation, or discharge and referral for follow-up. One should consider the potential lethality of the method chosen; for example, ingestion of a handful of birth control pills is less worrisome than shooting oneself or setting oneself on fire. It is also important to consider if the patient believed the attempt would result in death. Even if the method chosen was nonlethal from a medical standpoint (such as ingestion of antibiotics) but the patient believed it was lethal, the patient may be at risk for a future, more lethal attempt. Patients who plan and hide their suicide attempt may be more desperate to die than someone who makes the attempt in front of a family member and is rescued. In depressed patients, an intense sense of desperation is an important predictor of suicide.[98] Another important consideration in the evaluation of the suicidal patient involves the wish to live versus the wish to die. Not surprisingly, those patients with a wish to die are six times more likely to commit suicide than are those who wish to live.[99]

Although one should determine an individual patient's likelihood to commit suicide if discharged, this assessment is far from exact. No single psychological test can accurately predict suicide attempts.[100] In a group of 4800 psychiatric patients who were observed prospectively during 5 years, 44% of all suicides were not foreseen by the psychiatrist, and individuals who complete suicides after evaluation by an emergency psychiatric service have no specific factors that predict imminent suicide.[101,102]

There are at least 31 different English-language scales devised to predict the risk of suicide, but most are not designed for or suitable for use in the ED.[103] Some researchers are even using

www.ketabpezeshki.com 66485457-66963820

"fuzzy logic" and neural networks to achieve computerized prediction models for suicidality.[104] One study evaluated six clinical suicide assessment scales to identify high-risk patients: the Modified SAD PERSONS scale, revised Beck Depression Inventory, Beck Anxiety Inventory, Beck Hopelessness Scale, Beck Scale for Suicidal Ideation, and High-Risk Construct Scale.[105] All of the scales showed 100% sensitivity and negative predictive value but lower specificity (38-90%) and positive predictive value (28-71%). Although scoring systems might help in determining the need for hospitalization, they cannot predict future attempts at self-harm.[106,107] Nevertheless, an attempt to determine a patient's immediate risk of self-harm should occur and, when indicated, be communicated to other health care providers.

The SAD PERSONS mnemonic provides a "suicide score" (see Table 115-1) and is well suited for use in the ED. Two points are given for each of four high-risk factors: (1) complaints of depression or hopelessness, (2) existence of an organic brain syndrome or acute psychosis, (3) presence of a well-conceived plan or life-threatening presentation, and (4) expression of determination or ambivalence about future suicidal behavior. One point is assigned for other important but less significant factors: male gender; age younger than 19 or older than 45 years; a history of previous suicide attempts or psychiatric care; stigmata of chronic alcoholism or substance abuse or the history of recent increased use of these substances; a patient who is separated, divorced, or widowed; and the absence of social support systems, such as close family, friends, job, or active religious affiliation.

A SAD PERSONS score of 6 or more has a sensitivity of 94% and a specificity of 71% compared with formal psychiatric evaluation in identifying the need for hospitalization of patients who present immediately after a suicide attempt.[108] A score of less than 6 has a negative predictive value of 95%. No deaths at 6 to 12 months occurred in patients with low scores.

Another risk assessment tool used for adolescents is the Risk of Suicide Questionnaire.[109] The four most useful questions on the Risk of Suicide Questionnaire were the following:

Are you here because you tried to hurt yourself?
In the past week, have you been having thoughts about killing yourself?
Have you ever tried to hurt yourself in the past?
Has something very stressful happened to you in the past few weeks?

Any positive answer on this rapid screen correlated with potential risk for self-harm compared with a longer Suicidal Ideation Questionnaire, but correlation with actual suicidal outcomes is unknown.

Another simple scoring system is the British Manchester Self-Harm Rule, which uses four clinical correlates to determine future risk of suicide attempts[110]: (1) any history of self-harm, (2) previous psychiatric treatment, (3) benzodiazepine use in this attempt, and (4) any current psychiatric treatment. For 9086 patients, any positive answer on the four-question Manchester Self-Harm Rule had a sensitivity of 94% and specificity of 25% for a repeated attempt. How this rule would perform in a U.S. population with a far greater access to handguns remains unclear.

Suicide assessment should be performed after the patient metabolizes any drugs or alcohol. Intoxicated patients who complain of depression or state ambivalence about their future intentions to commit suicide may disavow these feelings once they are sober (but may still be at risk despite the disavowal). In addition, the information obtained from a potentially suicidal patient is best confirmed with a family member or friend as patients who are determined to commit suicide may give false or misleading information.

The crises that precipitate suicide attempts are often time limited, usually lasting a few hours to a few days. If a crisis has passed or can be adequately addressed, the risk of subsequent suicide is substantially diminished. Hospitalization or emergency psychiatric evaluation should be strongly considered when a patient cannot or will not participate in an evaluation of the current crisis or when the problem is unlikely to be resolved.

Ultimately, the assessment of suicide risk remains a highly individualized process considering the crisis that precipitated the suicide event, the patient's current emotional state, and the presence or absence of a supportive home environment. When emergency physicians are uncertain about the need for hospitalization, they should either admit the patient for psychiatric care or request emergency psychiatric evaluation. A psychiatric social worker or other paraprofessional may assist in gathering information and in making decisions about the need for hospitalization; however, the physician still should make an independent judgment about the patient's suicide risk.[111] Despite the medical-legal threats involved, nearly a quarter of emergency physicians occasionally send patients with suicidal ideation home without any evaluation by a mental health professional.[3]

Some investigators recommend hospitalization for adolescents who have attempted suicide and cannot be adequately monitored at home. However, discharge to home is an option for those with suicidal thoughts if urgent psychiatric follow-up is arranged and the caregivers can adequately supervise and protect the youth. Discharged adolescents should not be actively suicidal, should not have access to lethal methods, should have a supervising adult to closely monitor them, and should have a mental health evaluation before ED discharge whenever feasible.[72]

Involuntary Commitment

Some patients who are severely depressed or suicidal may resist hospitalization. Patients who refuse recommended medical treatment usually do so because of anger or fear. Patients may be angry for being brought to the ED against their wishes or for having to wait for evaluation. Alternatively, they may fear the loss of control associated with hospitalization or the perceived negative stigma associated with a psychiatric disorder. When a patient is reluctant to be hospitalized, the physician should attempt to identify and address the specific concerns. The patient's family and friends may help convince the patient to accept voluntary hospitalization. Involuntary admission may be necessary if the physician believes that the patient may inflict self-harm. Depression alone is not a criterion for involuntary commitment; the accepted legal standard requires the imminent risk of harm to self or others. In some states, even patients who voluntarily agree to hospitalization may need involuntary commitment papers filled out if they are an acute danger to self or others. This is to provide the legal basis for holding them against their will if they change their mind about hospitalization during the trip between the ED and the receiving psychiatric facility.

Civil commitment statutes differ among the 50 states and the District of Columbia. Nearly 85% of the jurisdictions require dangerousness to self to be the result of a mental illness, and only two jurisdictions mandate involuntary commitment if a person is an imminent harm to self.[112]

The efficacy of commitment as a long-term preventive measure is controversial.[99] Involuntary commitment is not proven to prevent future suicide and may even precipitate adverse psychiatric consequences (e.g., increased feelings of hopelessness and dependency) or cause rebellion in some patients. Many authorities believe that people who are determined to kill themselves will probably prevail despite the best efforts of family members and health care professionals.[7] Still, despite the lack of hard data, involuntary commitment remains a primary intervention when patients are deemed acutely suicidal.

www.ketabpezeshki.com 66485457-66963820

Pharmacology

There are no generally accepted or evidence-based protocols for drug treatment of suicidal thoughts in the ED. Antidepressants, lithium, and antipsychotics such as clozapine and olanzapine have been given to suicidal patients, but these are usually prescribed by psychiatrists and their effects occur during many weeks. ED pharmacology is usually directed to the treatment of agitation as needed, with use of a dose or two of a benzodiazepine or short-acting antipsychotic such as haloperidol, risperidone, or ziprasidone.

Ketamine

A number of studies suggest that intravenous (IV) administration of ketamine can rapidly decrease suicidal thoughts in depressed patients.[113-115] In one ED study, 20 patients with suicide ideation were administered a single dose of ketamine (0.25 mg/kg IV bolus during 3 minutes). Ketamine rapidly reduced both suicide ideation and depressive symptoms within hours with an effect sustained for up to a week.[116] Although it is promising, the use of ketamine in the ED to control suicidal impulses warrants further investigation before it can be considered a routine intervention.

DISPOSITION

Most patients at high risk for suicide will need psychiatric evaluation or hospitalization in a psychiatric facility. If patients require transfer to such a facility, they should be protected from self-harm during transport. Deaths from jumping from an ambulance during such transports have been reported.[117]

Many patients who attempt suicide or have symptoms of depression can be safely managed as outpatients if the risk of subsequent suicide is judged to be acceptably low (Box 115-2). Before discharging a patient, one should address the crisis that precipitated the suicide attempt. The patient should also be considered low risk for subsequent suicide (e.g., low SAD PERSONS score). Evaluation by a mental health professional is useful, especially if the safety of outpatient management is in doubt. Some physicians ask the patient to form a verbal or written "contract" with them. This "no harm" agreement usually involves patients' vowing not to hurt themselves and agreeing to return to the ED to seek help if the situation worsens before follow-up. Although the no harm agreement has not been validated, some believe that this is a reasonable approach, whereas others believe that it provides only a false sense of security for the physician. On its own, it will certainly not absolve the clinician from malpractice liability if the patient commits suicide.[118]

If the patient is to be discharged, a family member or friend should agree to stay with the patient or to be immediately available to the patient until follow-up is provided. The patient should be discharged to a stable and supportive home environment that is free of guns and lethal medications. Guns should be removed from the home by a trusted family member; gun locks or cabinets to which the patient has no key access may be a reasonable alternative.

Adequate disposition may include a conversation with the ongoing provider. The follow-up appointment should be scheduled within a few days of discharge and should be specific about the location and time. If possible, the follow-up should occur within 72 hours as suicide risk remains high shortly after discharge from the ED.[119]

Because a significant number of patients do not keep their follow-up appointments, compliance with follow-up may be increased by making a specific appointment for patients.[120] Having the family or friends help ensure that the patient keeps the follow-up appointment is another good strategy. In addition, it may also be helpful to provide a card that indicates how to contact an available physician.[121]

In one study, an ED-based "suicide intervention counselor" coordinated care and long-term follow-up. The counselor was able to decrease hospital readmissions for repeated suicide attempts by almost 10%.[122] Additional interventions that may improve the safety net for patients discharged from the ED include a follow-up phone call in 24 hours and home visits if patients do not keep their first appointment after discharge.[119]

Discharge instructions should include a statement that the patient should seek help immediately for suicidal thoughts. It may also be helpful to provide the phone number for the National Suicide Prevention Hotline resource: 1-800-273-TALK (8255). There is a special option for veterans to press after connecting to this number. The Hotline is a 24-hour, toll-free suicide prevention service, and calls are routed to the closest center. Some EDs provide Crisis Cards that patients can carry in their wallet, listing community resources to call when thoughts of suicide or depression loom.

Box 115-2 Factors for Patients at Low Risk for Suicide

- Few significant risk factors (e.g., low SAD PERSONS score)
- Stable and supportive home environment
- Patient agrees to "no harm" contract and will return to emergency department if situation worsens
- Family member or friend staying with or available to patient
- Phone contact with health care provider responsible for follow-up
- Specific appointment made for follow-up within 24 to 48 hours
- No gun in home
- Young woman who took a nonlethal ingestion or made "hesitation cuts" to wrists
- Patient expresses a strong desire to live

DOCUMENTATION

Documentation is especially important when patients are committed or discharged or when restraints are used. If a patient requires involuntary commitment, one should document why the patient is a danger to self or others. If the patient is discharged, the record should reflect that the patient is low risk and does not intend self-harm after leaving the ED. Documenting that there is no gun in the home is also useful. Preformatted charts may improve documentation.[123] Every time a patient is discharged from the ED after a suicide attempt or evaluation for suicidal ideation, the chart should reflect that the patient is at low risk for suicide.

PREVENTION

During the first 6 to 12 months after discharge from an ED, as many as 17% of suicidal patients reattempt suicide.[124] The incidence of suicide parallels the incidence of alcoholism, drug abuse, and psychiatric disease in society. Although most suicide prevention programs are of mixed value, legislation to control access to lethal drugs and handguns is effective. Laws requiring prescriptions for all sedative and hypnotic drugs in Japan led to a decrease in their use for suicide, with no increase in the use of other methods.[125] In Canada, suicide decreased after gun control laws were tightened.[126] Keeping a gun locked and unloaded and storing ammunition locked in a separate location are each associated with a protective effect against suicide by firearms in children and teens.[127]

Screening for suicidal ideation or depression may be a useful strategy. Physician education in depression recognition and

www.ketabpezeshki.com 66485457-66963820

treatment may reduce suicide rates.[94] Programs that screen for depression in the elderly[128] and school-based programs that screen for suicide risk in teens[129] may decrease suicidal ideation and suicide attempts. Occult suicidality is common in ambulatory ED patients who present for nonpsychiatric problems. In one study, waiting room patients were screened for suicidality with a computerized mental health assessment tool. Eleven percent had passive thoughts of suicide, and another 8% had active thoughts about killing themselves.[130] Whereas screening for occult suicide in all ED patients is an intriguing notion, the implications of referring 20% of all ED patients for psychiatric evaluation are staggering.

Contact of patients by telephone 1 month after their discharge from an ED for deliberate self-poisoning may reduce the number of reattempted suicides during 1 year.[131]

Despite great interest in the prevention of suicide, it is unclear which if any interventions are effective to prevent future attempts at self-harm.[132] No strong evidence suggests that antidepressants prevent self-harm in patients with prior suicide attempts; however, one small study did show an advantage to use of depot flupenthixol in multiple repeaters.[133] In another small study, dialectic behavior therapy was more effective than standard aftercare in preventing further episodes of self-harm.[134]

Suicide attempts correlate with future suicide. In one study of survivors of self-poisoning, the 5-year mortality rate from suicide was 65.5 times greater than expected in the female group (compared with a control group who did not attempt self-harm) and 41.5 times greater in the male group.[135]

KEY CONCEPTS

- Suicide is often provoked by a treatable or reversible short-term crisis.
- Suicidal patients frequently see a physician shortly before their death.
- The most complete information can be elicited with an empathetic approach to the patient and communication with family members, friends, health care providers, and others.
- Suicide precautions in the ED include appropriate use of "sitters" and, when necessary, physical and chemical restraints and involuntary commitment.
- The emergency physician should identify risk factors for suicide, even though determination of suicide risk is not a hard science. The SAD PERSONS score can be of help in documenting this assessment.
- Older men and those who attempt suicide with a firearm are at highest risk for a future completed suicide. Young women, especially those who cut themselves or take a nonlethal ingestion, are generally at lower risk.
- If patients are sent home because their risk of suicide is low, ensure a safe and supportive gun-free environment and early psychiatric follow-up.

Section Nine

IMMUNOLOGIC AND INFLAMMATORY

CHAPTER 116

ARTHRITIS

Nicholas Genes and Bruce D. Adams

PERSPECTIVE

Arthritis and its related disease states represent the most common cause of disability in the United States[1]; this is only expected to increase as the population ages and grows heavier. Because of the pain and limitations associated with joint inflammation, patients with complaints stemming from arthritis present frequently for emergent evaluation. Many of the arthritides are associated with premature mortality, and their treatments are associated with adverse effects. A systematic approach to evaluation of patients with arthritic complaints is important. The inflamed joint may be a diagnostic clue to a serious systemic illness (such as acute rheumatic fever or renal crisis), and unmasking of true arthritis emergencies can prevent or attenuate devastating disability.

Arthritis and related conditions are among the oldest disease states described. Roman, Greek, and Egyptian cultures made reference to gout and rheumatoid arthritis and even associated these maladies with diet and socioeconomic status. Gout was called the disease of kings because of its relationship to alcohol and rich foods.[2]

Many celebrated figures in medicine, such as Hippocrates, Galen, and Sydenham, contributed to the description, classification, and treatment of rheumatic disorders.[2,3] Reiter's syndrome, however, takes its name from a discredited Nazi war criminal (many, including the physician who first bestowed the eponym in the English literature in1942, now advocate for the generic term *reactive arthritis*).[4]

Several world leaders through the ages suffered from arthritis, and some have argued that specific flare-ups have shaped history.[2] Predisposing factors for gout, such as lead levels, may have influenced the rise and fall of civilizations.[5,6]

PRINCIPLES OF DISEASE

As opposed to synarthrotic suture joints of the skull and amphiarthrotic fibrocartilage unions like the pubic symphysis, the joints of concern in acute arthritis are the synovial or diarthrotic (moving) joints. These synovial joints are composed of two ends of subchondral bone covered by articular cartilage, surrounded by a capsule that is lined with a thin synovial membrane and supported by ligaments, tendons, and muscle (Fig. 116-1A).

Articular cartilage is an avascular, aneural tissue composed of a matrix of collagen fibers and proteoglycans synthesized by chondrocytes. The properties of articular cartilage allow tremendous load bearing. Together with the viscous lubricating synovial fluid, an ultrafiltrate of blood supplemented with hyaluronic acid and low-molecular-weight proteins, the cartilage that articulates joint movement is nearly frictionless.

Whereas disease-specific changes receive further detail in subsequent sections, the final common pathway of arthritis is triggered by trauma, infection, or the endogenous cell and humoral inflammation stimulated by infection or autoimmune disease.

The pathologic process of arthritis can unfold during hours or years. Tissue destruction can be mediated by fast-acting catabolic pathways, or long-term changes to the composition of cartilage's extracellular matrix may be brought on by abnormal loading patterns or trauma. The synovium plays a critical role in crystal deposition and inflammatory response (Fig. 116-1B).

CLINICAL FINDINGS

Symptoms and Signs

Pain is the hallmark complaint of patients with joint problems who come to the emergency department (ED) (Table 116-1). The pain may be acute or chronic (traditionally, more than 6 weeks) or an acute episode in a person with chronic disease. The patient may have had similar pain before, so it is important to know whether a diagnosis was previously made and what treatment, if any, was instituted. One must first determine whether the source of the inflammation or pain is articular or periarticular (outside the joint capsule).

True arthritis produces generalized joint pain, warmth, swelling, and tenderness. Discomfort increases with both passive and active motion of the joint because the inflamed synovium is exquisitely sensitive to stretching and because all parts of the joint are involved in the inflammatory process. By contrast, periarticular inflammation (bursitis, tendinitis, or localized cellulitis) tends to be more focal. Tenderness and swelling do not occur uniformly across the joint, and pain is produced only with certain movements, the most common being resisted active contraction and passive stretching of the affected muscles or tendons.

Patterns

If the site of the patient's pain is articular, the next step is to determine whether the arthritis is monarticular or polyarticular. The arthritis may be symmetrical (e.g., rheumatoid or drug induced) or asymmetrical (e.g., rubella, acute rheumatic fever, or gonococcal). In addition, it may also be migratory (e.g., gonococcal or rubella), subsiding in one area before presenting in another, or additive, remaining in the first joint and progressing to additional joints (Box 116-1).

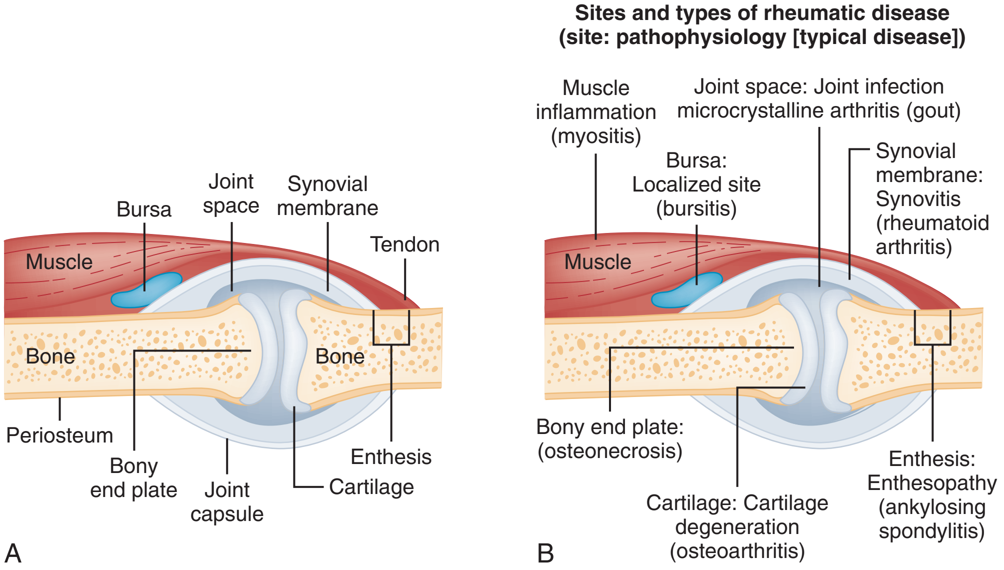

Figure 116-1. Anatomic structures of the joint with location of selected arthritis diseases. (Redrawn from Goldman L, Ausiello DA [eds]: Cecil Medicine, 23rd ed. Philadelphia, Saunders/Elsevier, 2008.)

Table 116-1 Causes of Joint Pain

MONARTICULAR	POLYARTICULAR	PERIARTICULAR
Acute (<6 weeks)		
Acute rheumatic fever	Gout	Bursitis
Lyme disease	Gonococcal arthritis	Tendinitis
Reactive arthritis (Reiter's)	Pseudogout	Cellulitis
Viral arthritis	Septic arthritis Trauma and hemarthrosis	Enthesitis
Chronic (<6 weeks)		
Adult-onset Still's disease	Osteoarthritis	
Relapsing polychondritis		
Rheumatoid arthritis		
Seronegative spondyloarthropathies		

Box 116-1 Differential Diagnosis of Arthritis in the Emergency Department

Monarticular
Septic arthritis
Gout
Pseudogout
Osteoarthritis
Trauma, hemarthrosis
Charcot's joint

Polyarticular
Symmetrical
Gonococcal arthritis
Viral arthritis
Lyme disease
Drug-induced arthritis
Reactive arthritis
Rheumatic fever
Seronegative spondyloarthropathies

Asymmetrical
Gonococcal arthritis
Acute rheumatic fever
Lyme disease
Systemic lupus erythematosus
Immune complex diseases (viral)
Reactive arthritis

Distribution and Associated Symptoms

The distribution of joint involvement may give some clues to the disease: the first metatarsophalangeal (MTP) joint is classically affected in gout; the metacarpophalangeal (MP) joints and proximal interphalangeal (PIP) joints in rheumatoid arthritis (RA); and the distal interphalangeal (DIP) joints and the first carpometacarpal joint in osteoarthritis (OA). Patients with inflammatory arthritis may have low-grade fever; high fever with chills is more suggestive of a septic arthritis. Morning stiffness (gel phenomenon) and improvement of symptoms with activity suggest inflammatory arthritis, whereas improvement with rest suggests mechanical disorders. Concomitant renal stones suggest gout; genital ulcerations occur in Behçet's disease and reactive arthritis; and a purulent urethral discharge suggests gonococcal arthritis or reactive arthritis. The use of isoniazid, procainamide, and hydralazine can precipitate lupus, and thiazides can increase the serum uric acid level, leading to gouty arthritis.

Physical Examination

General Examination. The physical examination searches for evidence of both local and systemic manifestations of rheumatic diseases (Table 116-2).

Joints. Joints are examined for warmth (the dorsum of the hand can detect a difference of 0.5° C), effusion, synovial thickening, deformity, range of motion, pain on actively loaded motion, and tenderness (generalized or localized, articular or periarticular).

Spine. The spine evaluation is best performed with the patient standing; the vertebral column is assessed for abnormal curvature or asymmetry. Although supporting evidence is scant, Schober's maneuver is used to assess for the limitation of the lumbar spine motion that occurs in ankylosing spondylitis.[7]

www.ketabpezeshki.com 66485457-66963820

Table 116-2 Clinical Signs of Arthritis Diseases*

ORGAN SYSTEM	FINDINGS	DISEASES
Airway	Airway obstruction	RA, RP
Cardiac	Pericarditis Murmurs	RA, ARF ARF, RP, AS
Eyes	Iritis, uveitis Conjunctivitis	Spondyloarthropathies Reactive arthritis
Gastrointestinal	IBD Dysentery	Spondyloarthropathies Reactive arthritis

Skin	Plaques on elbows, knees Sclerodactyly, calcinosis Erythema chronicum migrans Tophi Erythema marginatum Subcutaneous nodules	Psoriasis Scleroderma Lyme disease Gout Rheumatic fever Rheumatoid arthritis

*Excludes rheumatic vasculitis diseases.
ARF, acute rheumatic fever; *AS,* ankylosing spondylitis; *IBD,* inflammatory bowel disease; *OA,* osteoarthritis; *RA,* rheumatoid arthritis; *RP,* relapsing polychondritis.

Upper Extremities. Localized tenderness and pain associated with active movement are more likely to be periarticular in origin. A shoulder affected by chronic arthritis or bursitis will have atrophy of the deltoid muscle. Generalized tenderness and pain, both at rest and with active and passive motion, suggest joint involvement.

Early signs of joint inflammation in the elbow are limitation of extension and an increase in the normal angle at which the patient holds the elbow at the side.

The hand and wrist provide many clues to the presence of long-standing rheumatic diseases: MP and PIP joints are affected in RA; and the first carpometacarpal, PIP, and DIP joints are affected in OA. The fingers may be swollen or sausage-like in appearance, an indication of psoriasis or reactive arthritis. Subluxation at the MP joints, ulnar deviation, and swan-neck deformities occur in RA. The nails may have pitting characteristic of psoriatic arthritis.

Assessment of the wrist is difficult because it may not be obviously swollen. Discomfort and decreased range of motion, particularly on extension, may indicate synovial involvement.

Lower Extremities. Inflammation affecting the hip joint can be manifested as pain in the anterior thigh, knee, or groin. A hip joint effusion will cause the patient to hold the hip partially flexed. An externally rotated and abducted leg in a neonate strongly suggests infection.[8] Range of motion of the hip is most easily tested by flexing the hip, bending the knee at a right angle, and rotating the heel medially and laterally to test for external and internal rotation, respectively.

Box 116-2 Radiograph of a Joint Can Be Surveyed by This Systematic Approach

A Alignment: Rheumatoid arthritis is manifested with ulnar deviation.
B Bone mineralization: Osteoporosis is more typical of the inflammatory arthritides; periostitis (reactive bone formation) indicates seronegative spondyloarthropathies or osteoarthritis.
C Calcification: Gouty tophi and typical linear cartilage calcification of CPDD.
D Distribution: Rheumatoid arthritis is typically symmetrical. Specific target sites suggest diagnoses.
E Erosions: Overhanging edges and sclerosis are characteristic of gout.
S Soft tissue: Assess for soft tissue swelling, nail hypertrophy (psoriatic arthritis), and sclerodactyly (scleroderma).

An effusion of the knee joint is relatively easy to detect when it appears as a ballotable fullness medially and laterally. Fullness of the popliteal fossa may indicate Baker's cyst. Passive range of motion may elicit crepitus (suggestive of degenerative joint disease) or clicking (suggesting a meniscal tear). Tibiotalar joint effusions produce swelling under the medial malleolus and make it difficult to palpate the extensor hallucis longus tendon. Tenderness, warmth, and swelling of the great toe MTP joint occur in cases of gout but can also occur with OA and RA. Sausage-like swellings of the toes are seen in reactive arthritis.

DIAGNOSTIC STRATEGIES

Blood Tests

In the ED evaluation of arthritis, blood testing conveys only modest diagnostic value.[9] The erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) serum level, white blood cell (WBC) count, and serum uric acid level are best used in the context of evaluating the likelihood of specific forms of arthritis; there are no guidelines or studies supporting the use of blood testing as a general screen of acute undifferentiated arthritis in the ED.

Radiologic Tests

Plain Radiography

Plain radiographs are more helpful in patients with chronic disease than in those with acute arthritis (Box 116-2). Common findings that help distinguish the different forms of arthritis are shown in Table 116-3. For lower extremities, weight-bearing radiographs can better evaluate joint space narrowing.

Computed Tomography, Magnetic Resonance Imaging, and Sonography

Other radiologic modalities are occasionally performed as part of the workup of arthritis in an emergency setting. Ultrasonography compares favorably with plain radiography in the evaluation of joint effusions and synovitis associated with RA, and it is useful to evaluate pediatric hip effusion and to guide arthrocentesis.[10] Magnetic resonance imaging (MRI) is well suited for imaging of cruciate ligaments of the knee, detection of early edema in periarticular structures and fluid collection in tendon sheaths, and determination of the extent of cartilage destruction.[11] MRI is also the study of choice for diagnosis of osteonecrosis and is more sensitive than plain radiography for early osteomyelitis.[12,13]

www.ketabpezeshki.com 66485457-66963820

Table 116-3 Common Radiologic Findings in Arthritis

ARTHRITIS	FINDINGS
Acute arthritis (gout, pseudogout, septic arthritis)	Soft tissue swelling
Late septic arthritis (need at least 8-10 days for changes to be seen)	Subchondral bone destruction Periosteal new bone Loss of joint space Osteoporosis Late joint space narrowing
Late pseudogout (knee, hip; radiocarpal, midcarpal, all MP joints)	Linear calcification in cartilage Asymmetrical joint space narrowing MP "hook spurs" in HHC Osteophyte formation Subchondral cyst formation Lack of osteoporosis
Degenerative arthritis (acromioclavicular, first carpometacarpal, first MTP, DIP joints; knee, hip, cervical spine, lumbosacral spine)	Asymmetrical joint space narrowing Sclerosis of juxta-articular bone Bone spurs and cysts—adjacent to severe cartilage degeneration No osteoporosis
Tuberculous arthritis (knee, hip, shoulder)	Soft tissue swelling Marked demineralization Bone rarefaction Little reactive sclerosis Late bone destruction Joint space preserved
Late rheumatoid arthritis (wrist, MP, PIP, MTP, first IP joints; foot, atlantoaxial joint, glenohumeral joint)	Symmetrical joint space narrowing Osteoporosis of periarticular bone Marginal erosions (no overhanging margins as in gout) Little reactive bone formation

DIP, distal interphalangeal; *HHC*, hereditary hemochromatosis; *IP*, interphalangeal; *MP*, metacarpophalangeal; *MTP*, metatarsophalangeal; *PIP*, proximal interphalangeal.

Arthrocentesis

Arthrocentesis is a crucial diagnostic modality because it is the only method of unequivocal diagnosis of septic arthritis or crystal-induced joint disease.

Indications and Contraindications

The emergency indications for arthrocentesis in the evaluation of joint pain are to obtain joint fluid for analysis, to drain tense hemarthroses in patients with trauma or hemophilia (of the elbows, knees, or ankles and after the appropriate clotting factor replacement), to evaluate whether a laceration communicates with the joint space, and to instill analgesics and anti-inflammatory agents for the treatment of acute and chronic arthritis.

The American College of Rheumatology guidelines recommend arthrocentesis to evaluate patients with an established history of arthritis who present with fever and new joint pain or effusion.[14] Although scant literature on inoculated joint spaces exists, emergency arthrocentesis through overlying cellulitis is relatively contraindicated, and avoidance of the infected area during the puncture is recommended. Coagulopathy is the other relative contraindication, but arthrocentesis can be safely performed with a 20- to 22-gauge needle in the presence of international normalized ratios as high as 4.5.[15] Arthrocentesis of prosthetic joints should be performed only to rule out infection and is best done in consultation with an orthopedic surgeon.

Complications

The primary complications of arthrocentesis are bleeding or infection in the joint space, allergic reaction to anesthetic agents, and long-term corticosteroid-related complications. Dry taps (when no fluid is aspirated after joint puncture) are more common in patients with chronic arthritis because of obstructing tophi or anatomic abnormalities in the synovium and periarticular tissues. Use of a smaller syringe or a larger needle may help in such cases. Many laboratories will accept just a single drop of synovial fluid for use in crystal analysis on a slide mount.

Technique

Successful joint aspirations begin with positioning of patients so they are comfortable, with adequate exposure and cushioned support for the joint. Muscle tension during the procedure can reduce the joint volume, making the procedure more difficult. Carefully palpate the bone landmarks and prepare the skin with an aseptic technique. Adequate local anesthesia is achieved either by use of a vapor coolant or by local infiltration with anesthetic solution, such as 1% or 2% lidocaine. With an 18- or 19-gauge (large joints) or 20- to 22-gauge needle (smaller joints) attached to a syringe, the joint space is punctured and aspirated with care taken to avoid abrasion of the articular cartilage. Excessive suction may bring synovial tissue into the needle, limiting aspiration. After aspiration, a long-acting anesthetic can be instilled to alleviate pain. As a general rule, do not instill steroids unless a septic arthritis has been excluded.

Synovial Fluid Examination

Analysis of synovial fluid is essential for identification of crystalline and suppurative causes of acute arthritis (Table 116-4).

General Appearance. Bedside inspection of synovial fluid for color, clarity, and viscosity can provide diagnostic clues. Normal synovial fluid is clear and colorless, with a viscosity that permits stretching of a "string" of fluid between the thumb and forefinger. Inflamed fluid is more opaque from an elevated WBC count, with a viscosity more like water because of enzymatic breakdown of glycosaminoglycans. Hemarthrosis is manifested after acute trauma or in the presence of coagulopathy, particularly with hemophilia. Lipohemarthrosis indicates ligamentous injury or an intra-articular fracture, and brownish synovial fluid may suggest the rare diagnosis of pigmented villonodular synovitis.

Synovial Fluid Studies. Routine laboratory analysis includes a cell count with differential, Gram's stain, and crystal analysis; synovial glucose and protein concentrations are of little diagnostic assistance.[16] A positive Gram's stain is diagnostic, but a negative result for bacteria does not rule out septic arthritis; culture specimens should also be obtained. Blood culture bottles are more sensitive than other media at identification of pathogens.[17,18]

Synovial White Blood Cell Count. Synovial WBC (sWBC) counts are often used to differentiate classes of synovial fluid; unfortunately, significant overlap exists between inflammatory and septic causes of acute arthritis.[17] A very high fluid sWBC count or polymorphonuclear (PMN) cell pleocytosis indicates infection, but a more modest sWBC count or differential does not exclude it. The likelihood ratio (LR) for septic arthritis increases as the joint WBC count rises. According to one review, sWBC count of less than 25,000/mm^3 = LR of 0.32; sWBC count of more than 25,000/mm^3 = LR of 2.9; sWBC count of more than 50,000/mm^3 = LR of 7.7; and sWBC count of more than 100,000/mm^3 = LR of 28.0.[9] However, low sWBC counts do occur early in infectious arthritis and in partially treated infections; high sWBC counts (>50,000/mm^3) can occur in RA, gout, and pseudogout. Most of

PMNs, polymorphonuclear cells; *WBCs,* white blood cells.

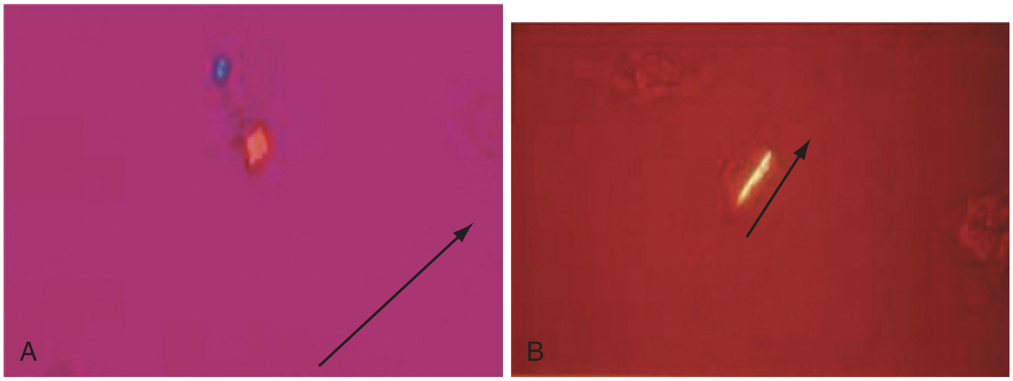

Figure 116-2. Pseudogout (**A,** blue crystal with a more plump structure) and gout (**B,** yellow crystal in parallel refraction with a longer, more needle-like structure) crystals under polarizing light. (From Goldman L, Ausiello DA [eds]: Cecil Medicine, 23rd ed. Philadelphia, Saunders/Elsevier, 2008.)

the cells in both septic and severe inflammatory arthritis are PMN cells.

In summary, cell counts cannot be used to absolutely rule out a septic cause. When in doubt, bacterial cultures sent in blood culture bottles are recommended.

Crystal Analysis. Although there is some variation in study findings, overall there is an acceptable inter-rater reliability in identifying monosodium urate and calcium pyrophosphate dihydrate crystals in acute arthritis.[19] Crystal analysis is best performed by polarizing microscopy of a fresh drop of synovial fluid placed on a slide with cover slip (Fig. 116-2). Monosodium urate crystals are needle shaped and strongly negatively birefringent (yellow when parallel to the compensator and blue when perpendicular), ranging in size from 2 to 10 μm. Calcium pyrophosphate crystals, in contrast, are polymorphic, rhomboid, and positively (although weakly) birefringent. Lipid appears as a spherule with a Maltese cross, and hydroxyapatite is difficult to recognize.

DIFFERENTIAL CONSIDERATIONS AND MANAGEMENT

Monarticular Arthritis: Acute

Inflammatory conditions of the periarticular soft tissues, such as olecranon bursitis, rotator cuff shoulder tendinitis, and prepatellar bursitis, can mimic monarticular arthritis, and classically polyarticular conditions, such as RA and the seronegative spondyloarthropathies, may present initially in only one joint. As a general rule, a patient presenting with monarticular arthritis has a septic arthritis until it is determined otherwise (Fig. 116-3).[20]

Septic Arthritis: Nongonococcal Bacterial

Epidemiology. In two prospective series of patients presenting to the ED with monarticular arthritis prompting arthrocentesis, 8 to 27% of patients had bacterial joint infections.[16,21] The incidence of septic arthritis in the general population is approximately 2 to 10 cases per 100,000 per year, with an age distribution curve for septic arthritis revealing bimodal peaks for young children and adults older than 55 years.[22] Additional risk factors include low socioeconomic status, injection drug abuse (in which joint infections typically involve the axial skeleton but can involve extremities), alcoholism, diabetes, skin infections, advanced human immunodeficiency virus (HIV) infection or other immunocompromised states, chronic arthritis (particularly rheumatoid, crystalline, and degenerative OA), and following intra-articular corticosteroid injections or prosthetic implants.

Pathophysiology. Any diarthrotic joint, whether it is native, chronically diseased, or prosthetic, can develop septic arthritis. Bacterial pathogens infect the joint space most commonly by hematogenous spread, but direct inoculation and contiguous spread from bone or soft tissue infections also occur. Once in the joint, bacteria proliferate essentially unchecked in the highly vascular synovium, which has no limiting basement membrane. Bacterial components and toxins, as well as the inflammatory cascade they induce, trigger synovial proliferation with neovascularization and subsequent enzymatic, cellular, and cytokine degradation of articular cartilage. Septic arthritis, unless it is rapidly recognized and treated, results in serious disabling morbidity, with mortality ranging from 7 to 15% or higher.[17]

Septic arthritis can occur simultaneously with other forms of arthritis, especially RA and gout.[20] The diagnosis of infectious

www.ketabpezeshki.com 66485457-66963820

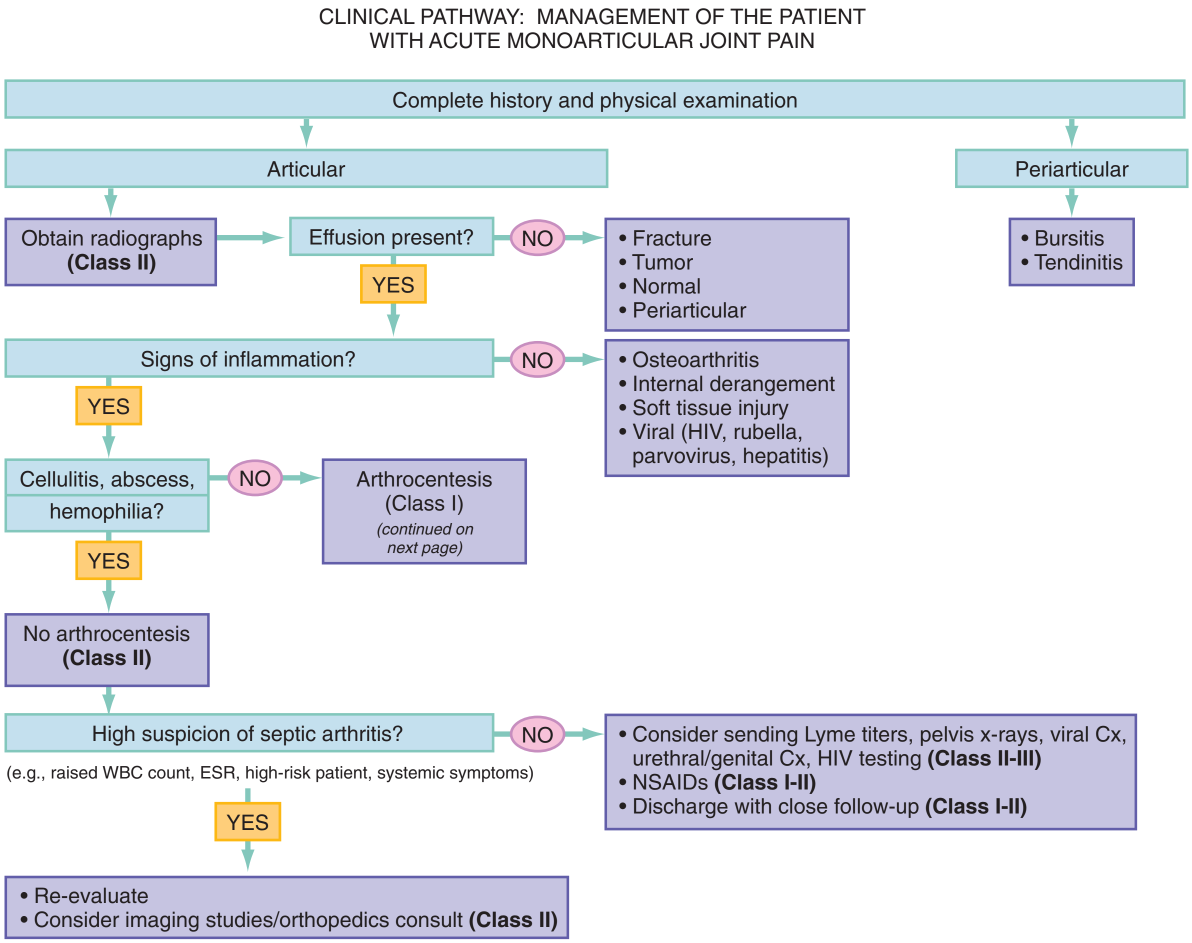

Figure 116-3. An initial approach to the patient with monarticular arthritis. The majority of diagnoses will be determined by the history and physical examination findings. *CBC,* complete blood count; *Cx,* culture; *ESR,* erythrocyte sedimentation rate; *HIV,* human immunodeficiency virus; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PT/PTT,* prothrombin time/partial thromboplastin time; *WBC,* white blood cell. (Modified from EB Practice LLC. 2004.)

arthritis in a patient with known crystal arthritis can be challenging because acute flare-ups of gout or pseudogout can cause fever, and crystals can emerge from an infected joint. For this reason, Gram's stain and culture should be considered in select cases.

Microbiology. The microbiology of nongonococcal arthritis has remained fairly constant over time, except for the notable decline of *Haemophilus* and pneumococcal species in the postimmunization era.[22] Acute nongonococcal septic arthritis in adults is caused most often by gram-positive organisms (75-90%), followed by gram-negative bacilli (10-20%) and then anaerobes, mycobacteria, and fungal and other unusual organisms.[23] Overall, *Staphylococcus aureus* is still the most common cause of septic arthritis, with the rapid emergence of methicillin-resistant strains.[24] *Neisseria gonorrhoeae* accounts for only 20% of cases of monarticular septic arthritis and more commonly is manifested with polyarthritis; it is discussed separately. Select populations have higher propensities for specific infecting organisms (Table 116-5).

Prosthetic Joint Infection. Prosthetic joint infections are classified as early (within a month of surgery) or late. Late infections can be caused by hematogenous spread from another infection or by indolent organisms introduced at surgery that may not surface for up to a year.[25] Because the joint is literally replaced, antibiotic bioavailability and host immune response are both impaired in the prosthetic environment. A wide range of culprit organisms have been identified[26]; methicillin-resistant *S. aureus* (MRSA) incidence is rising.[27] Arthrocentesis diagnosis of a suspected prosthetic joint infection is best done in consultation with the operating surgeon. A fluid WBC count of more than 1100/mm^3 or a pleocytosis of greater than 64% PMN cells is sensitive and specific for infection in this setting.[28]

Clinical Features. Patients with septic arthritis present with fever, joint pain, and effusion, typically in a single large joint (the knee is most common). Moderate fever occurs in 50% of cases[17] but may be less common in the presence of advancing age or immunosuppressive states.[17] Rigors and chills are reported in only 20% of patients. Polyarticular presentation occurs in 20% of cases, particularly in patients with RA or chronic joint disease, meningococcal infections, or overwhelming sepsis.[17] Other physical signs, such as edema, tenderness, and decreased range of motion, have not been adequately evaluated for their prognostic value.

Diagnostic Strategies. Laboratory evaluation typically includes complete blood cell count, ESR, and CRP level, although in one study a WBC count above 10,000/μL and an ESR above 30 mm/hr only minimally increased the likelihood of septic arthritis.[28] Furthermore, systematic reviews show insufficient evidence for a normal CRP level, ESR, WBC count, or procalcitonin level to rule out septic arthritis.[29,30] Serum blood cultures reveal the causative organism approximately 25 to 50% of the time.[31,32]

Radiographs demonstrate only soft tissue swelling if it is present; the bone changes of septic arthritis are long-term findings and are not usually present on the initial examination. Radiographs are recommended to assess for osteomyelitis or as a baseline for future comparisons.

GNR, gram-negative rod bacteria.

The only definitive diagnostic test for septic arthritis is synovial fluid analysis. The fluid WBC count is directly proportional to the probability of a septic joint. Polymorphonucleocyte concentrations above 90% are also associated with an increased likelihood for septic arthritis. Synovial lactate levels greater than 5.6 mmol/L have an LR+ of 2.4 to infinity; smaller values make septic arthritis unlikely.[33] Synovial lactate dehydrogenase (LDH) levels above 250 U/L are sensitive for septic arthritis, according to one study,[16] whereas LDH levels below this seem to exclude septic arthritis. Low synovial glucose and high protein concentrations are neither sensitive nor specific for septic arthritis.[32] Gram's stain will show bacteria in 50 to 80% of infected joints.[17] Synovial fluid cultures for both aerobic and anaerobic organisms should be performed.

Management. The key to successful treatment of nongonococcal septic arthritis is early diagnosis. Substantial delays in diagnosis directly worsen prognosis. Empirical antibiotic therapy is based on Gram's stain or the presumptive consideration of likely organisms. Once the diagnosis is made, hospital admission is indicated for administration of intravenous antibiotics and needle, arthroscopic, or open drainage of the affected joint.[34] Whereas the utility of performing or omitting joint drainage has not been prospectively studied, retrospective reviews suggest good cure rates with drainage, with outcomes dependent on initial severity.[35] More severe cases require frequent, potentially daily joint aspirations.

There are no randomized controlled trials of antibiotic regimens in septic arthritis. Antibiotic selection is initially based on

www.ketabpezeshki.com 66485457-66963820

Gram's stain results and then adjusted on the basis of final culture results and sensitivities. For gram-positive organisms, the initial drug of choice is vancomycin 30 mg/kg daily in two divided doses as MRSA is frequently causative.[24] For gram-negative bacilli, use a third-generation cephalosporin, such as ceftriaxone 2 g IV once daily, cefotaxime 2 g IV three times a day, or ceftazidime with gentamicin (especially if *Pseudomonas* infection is suspected). Although no trials of antibiotic duration have been reported, antibiotic therapy is generally continued parenterally for 2 to 4 weeks, depending on the response, and followed with 2 to 6 weeks of oral antibiotic therapy.

The failure to respond to therapy within a few days of hospitalization, the presence of osteomyelitis, the involvement of the hips or shoulders, or the involvement of any prostheses usually mandates open arthrotomy for drainage. Parenteral opioid analgesics and immobilization are recommended for pain and discomfort.

Gonococcal Arthritis

Principles of Disease. Gonococcal arthritis was considered the most common infective arthritis in the United States in the 1970s and 1980s and remains the most common form of joint infection in the sexually active population. In recent years, the incidence has decreased, most likely because of a general decline of *N. gonorrhoeae* prevalence, particularly of the more virulent strains.[36] Host risk factors for dissemination of gonococcal infection to joints include pregnancy, menstruation, and complement deficiency. There is a 4 : 1 female predominance, possibly explained by mucosal infections more often being asymptomatic in women.

Gonococcal arthritis represents a clinical and pathologic course distinctly different from that of other bacterial infections and is less likely to create long-term joint disease.[25]

Clinical Features. Systemic gonococcal infection complicates 0.5 to 3% of mucosal infections and is manifested with two somewhat overlapping musculoskeletal syndromes. The first is a localized septic arthritis, more commonly oligoarthritis than monarthritis, predominantly in the wrist, knee, or ankle. The effusions may be modest. True disseminated gonococcal infection (sometimes termed arthritis-dermatitis syndrome) is manifested with bacteremia, diffuse migratory arthralgias, characteristic skin lesions, and tenosynovitis (Fig. 116-4). A similar syndrome has recently been recognized as a result of *Neisseria meningitidis* infection.[37]

Management. Microbiologic diagnosis is a problem because both synovial and blood cultures are positive for gonococcus in no more than 10 to 50% of cases.[25] The diagnostic yield is higher when specimens are plated on Thayer-Martin medium and even greater with the use of polymerase chain reaction. Synovial fluid often yields a positive Gram's stain result, and the synovial WBC count tends to be lower than in nongonococcal arthritis (40,000-60,000 cells/mm^3). Cervical, urethral, rectal, and pharyngeal cultures are positive in up to 75% of cases, so all mucosal orifices of the patient (and partner, if possible) should be cultured appropriately.[36] In disseminated gonococcal infection, the skin lesions often contain the gram-negative diplococcus.

The current Centers for Disease Control and Prevention (CDC) guidelines recommend hospitalization, especially if etiology or compliance is uncertain, and treatment with intramuscular or intravenous ceftriaxone 1 g every 24 hours or intravenous ceftizoxime or cefotaxime 1 g three times daily, with transition to oral cefixime 400 mg twice daily for at least a week.[38] Partners should be evaluated. Presumptive treatment of *Chlamydia* is also advised.

Repeated therapeutic arthrocentesis need not be as aggressively used in this form of septic arthritis. With prompt antibiotic therapy, residual joint problems are uncommon.

Figure 116-4. Pustular lesion with disseminated gonococcal infection. (From Mandell GL, Bennett JE, Dolin R [eds]: Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, 6th ed. Philadelphia, Elsevier/Churchill Livingstone, 2005.)

Gouty Arthritis

Epidemiology. Acute intermittent gout typically is manifested in middle-aged men or postmenopausal women, often in the setting of excess alcohol consumption or dietary indiscretion, acute physiologic stressors (such as illness, trauma, or surgery), or new medications. Its prevalence in the United States is estimated at 2.7% of the population. Risk factors include chronic obesity, hypertension, diabetes, thiazide diuretics or cyclosporine use, and lead or radiocontrast exposure. Purine-rich diets (meat; seafood, especially anchovies and shellfish; beer; and legumes) predispose at-risk individuals to attacks; high-fructose corn syrup and soft drinks are also implicated.[39] High dairy and coffee consumption have been shown to decrease risk.[40]

Pathophysiology. Gout results from inflammation caused by the acute precipitation of uric acid crystals from supersaturated extracellular fluid. Uric acid is a normal metabolic end product of purine metabolism. Hyperuricemia results from its underexcretion in the kidney or, less commonly, from systemic overproduction caused by inborn errors of metabolism and myeloproliferative diseases. During an attack of gouty arthritis, the crystals are ingested by PMN cells, resulting in cytokine release and an inflammatory synovial reaction.

Asymptomatic hyperuricemia typically exists for decades, and less than a quarter of these patients have acute manifestations. Furthermore, not all patients with elevated uric acid levels or even joint crystals have acute attacks, and many patients with an acute gouty arthritis have a normal uric acid level.[41]

Clinical Features. Gouty attacks most commonly occur in the great toe MTP joint (*podagra,* up to 75%, with 90% of patients eventually experiencing this joint flare), the knee (*gonagra*), the ankle, and the tarsal joints. Usually only one joint is involved initially, but approximately 20% of patients can experience polyarticular involvement, bursitis, tenosynovitis, or even skin inflammation.[42] The pain is often so exquisite at onset that some patients cannot even tolerate the weight of a sheet on the joint. Systemic symptoms range from absent to dramatically mimicking a picture of septic arthritis. Fever can occur. Without treatment, the attack is self-limited, peaking during 24 to 48 hours and lasting about a week.

Subsequent attacks tend to be closer together, involve more joints, and last longer, eventually morphing into the final stage of chronic gouty arthritis after a decade, if untreated. Long-term sequelae include renal stones and tophi in the musculotendinous units, such as the olecranon bursa, Achilles tendon, ulnar surface

www.ketabpezeshki.com 66485457-66963820

of the forearm, hands and fingers, knees, feet and toes, and even the helix of the ear. The ED patient may present with a first attack or have a known history of gout with a recurrent episode. Cellulitis and septic arthritis need to be excluded, particularly if the knee is involved.

Diagnostic Strategies. During an acute attack, radiographs of the affected joint will show only soft tissue swelling, but long-standing disease produces typical asymmetrical bone erosions slightly removed from the joint (as opposed to RA erosions, which are more proximal to the articular surface). The crystal deposits of gout also cause an overhanging margin of soft tissue by the erosion.[43] Dual-source, dual-energy computed tomography using a mineral composition algorithm has shown promise in a small trial for diagnosis of uric acid collections in joints; blinded radiologists were able to match 12 positive images to 12 positive joint aspirations for gout; specificity was also good.[44]

Whereas higher levels of serum uric acid are commonly seen in gouty patients, this laboratory finding is not helpful in establishing the diagnosis of gout in the acute setting. Urate levels can be transiently normal, a process thought to be mediated by the uricosuric effects of endogenous adrenocorticotropic hormone (ACTH) and epinephrine, released as part of the pain response. Given the association of gout and renal insufficiency and the nephrotoxicity of several therapies, renal function should be checked.

The observation, with a polarizing microscope, of intracellular negatively birefringent crystals in joint fluid aspirate (see Fig. 116-2) remains the "gold standard" for diagnosis of gouty arthritis.

Management. Gout therapies are divided into acute treatment modalities and long-term prophylaxis. Prophylaxis is generally not an emergency consideration, but many patients present with breakthrough attacks. Traditionally, it has been recommended that prophylactic agents such as allopurinol, febuxostat, and probenecid neither be stopped nor initiated during an acute attack.[45]

ED pharmacologic mainstays for acute gout are nonsteroidal anti-inflammatory drugs (NSAIDs, including cyclooxygenase 2–selective agents), corticosteroids (including ACTH), and colchicine. Caution is exercised with use of these agents because hypertension, diabetes, and renal and vascular disease are prevalent in this cohort of patients.

NSAIDs. Whereas NSAIDs, particularly indomethacin, are considered first-line therapy for acute gout attacks, there is little evidence to support their superiority over other agents, and trials between NSAIDs have shown no apparent difference in efficacy.[46,47]

For acute attacks, indomethacin is typically given at 50 mg three times a day, naproxen at 500 mg twice a day, and ibuprofen at 800 mg three or four times a day.[48] If NSAID therapy is initiated promptly, relief occurs rapidly in the first 24 hours. Duration should continue for another 24 hours after the symptoms abate and be tapered quickly; longer durations may be necessary if treatment is delayed.

Colchicine. Colchicine inhibits microtubule formation and impedes the inflammatory response to the presence of crystals in synovial fluid. Its use for gout predates the foundation of the Food and Drug Administration in 1938,[48] but the promise of government-sanctioned market exclusivity has prompted new trials for safety and efficacy. Oral colchicine has been shown to be highly effective for gout in small randomized placebo-controlled trials at a loading dose of 1 mg followed by 0.5 mg orally every 2 hours.[49] However, all patients studied with colchicine at these doses eventually had gas, nausea, vomiting, or diarrhea. In 2010, a prospective double-blind study of an oral loading dose of 1.2 mg colchicine followed by 0.6 mg an hour later demonstrated superior pain relief of colchicine over placebo, and the low-dose regimen demonstrated pain relief similar to that with a high-dose regimen of 4.8 mg administered during 6 hours. The low-dose regimen also had a lower incidence of gastrointestinal complaints. Lower dosing is recommended in elders; in several case reports, dosing of colchicine at 0.6 mg spread over three times a day has been effective for pain relief as well.[49]

Colchicine is also effective in relieving symptoms from other crystal arthritides and therefore is not helpful when it is used for diagnostic purposes.[50]

Colchicine is contraindicated in patients with hematologic, renal, and hepatic insufficiency. Intravenous colchicine is generally not recommended, despite its rapid onset and reduced gastrointestinal toxicity. Intravenous colchicine has a long half-life and narrow therapeutic window; more than 20 iatrogenic deaths have now been reported across a broad spectrum of ages.[51]

Steroids. Once septic arthritis has been excluded, the intra-articular injection of steroids may be effective for individuals with accessible joint involvement; in one series of patients with contraindications to NSAIDs, pain relief was demonstrated within 48 hours of injection of 10 mg triamcinolone acetonide.[52] Triamcinolone acetonide in a dose of 20 to 40 mg for the knee and 5 to 10 mg for smaller joints is recommended.[53]

Systemic steroids, such as oral prednisone (40 mg/day for 3-5 days, with or without a taper), have been used.[54] However, a Cochrane review of three trials of various steroids against other agents failed to demonstrate evidence of efficacy for systemic steroids.[55] The authors of that review undertook a randomized trial of Dutch patients with arthrocentesis-confirmed gout who had not taken pain medications before diagnosis and found similar efficacy for pain relief from oral prednisolone 35 mg daily compared with naproxen 500 mg twice daily during 90 hours.

Adrenocorticotropic Hormone (Corticotropin). Although it is not commonly used (or studied) because of its expense and lack of general availability, synthetic ACTH is a desirable alternative to the preceding agents because of its fast onset of action and decreased toxicity in older patients.[56,57] In one randomized trial, it was found to achieve faster pain relief than indomethacin, with fewer side effects at a dose of 40 IU intramuscularly.[57] It is not considered likely that a single administration of ACTH will cause hypothalamic-pituitary-adrenomedullary axis suppression.

Other Agents. Guidelines for management of acute gout recommend that if the flare occurs while a patient is receiving a diuretic, the diuretic should be stopped if at all possible.[49] Narcotic analgesics and either local or regional anesthetic blocks are potential adjunctive therapy. Clinicians should remember that simple physical modalities, such as rest, elevation, and ice, demonstrate modest benefit and are adjunctive measures for any therapeutic regimen.

Summary. Both NSAIDs and colchicine are considered first-line therapies for gout; the two are often used in tandem in patients without contraindications, particularly renal insufficiency. Best available evidence supports a treatment strategy of prompt initiation of NSAID therapy (e.g., 50 mg of indomethacin three times daily or 500 mg of naproxen twice daily) or colchicine 1.2 mg followed by a 0.6-mg dose an hour later.

Patients for whom NSAIDs or colchicine is contraindicated can be treated with intra-articular injections of triamcinolone or ACTH (corticotropin). Systemic steroids, although commonly used, have a weaker evidence base, but a recent trial suggested that prednisolone 35 mg/day is comparable to naproxen 500 mg twice a day during the course of 4 days.

Follow-up, preferably with a rheumatologist, is recommended for proper prophylaxis against flares and risk mitigation.

Calcium Pyrophosphate Dihydrate Deposition Disease and Pseudogout

Principles of Disease. Calcium pyrophosphate dihydrate deposition disease (CPDD) results when calcium complex crystals form

www.ketabpezeshki.com 66485457-66963820

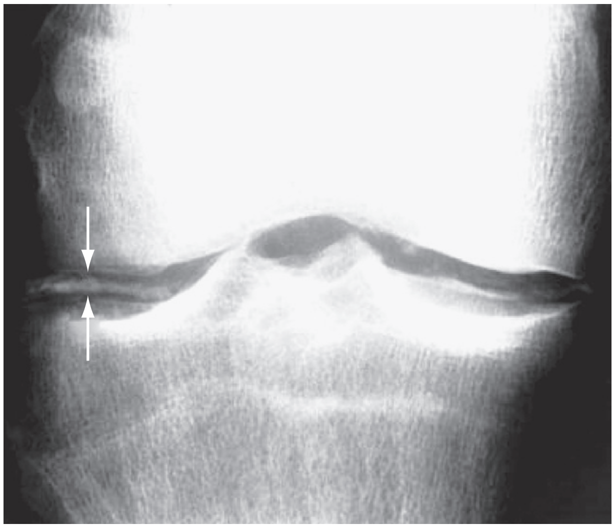

Figure 116-5. Chondrocalcinosis (*arrows*) in calcium pyrophosphate dihydrate deposition disease. (From Mettler FA: Essentials of Radiology, 2nd ed. Philadelphia, Saunders/Elsevier, 2005.)

across articular surfaces, manifested on radiographs as chondrocalcinosis (Fig. 116-5). The pathologic mechanisms are incompletely understood but involve overproduction of chondrocyte pyrophosphate, increased calcium, and histologic changes in the cartilage's extracellular matrix. CPDD is strongly associated with aging and joint surgery, but hemochromatosis, hypothyroidism, hyperparathyroidism, amyloidosis, hypomagnesemia, Wilson's disease, and inflammatory OA have also been implicated. The condition is most often asymptomatic, and its true incidence is unknown, but when precipitating crystals create an inflammatory synovitis, in about a quarter of cases, it is properly termed pseudogout.

Clinical Features. The clinical presentation of CPDD is similar to that of gout, and indeed the two conditions may overlap, thus making a synovial fluid diagnosis important. Pseudogout patients tend to be older than 65 years, and the knee is more commonly involved.

Diagnostic Strategies. Diagnosis of CPDD and pseudogout involves demonstration of the characteristic synovial crystals and radiographic changes. Radiographs demonstrate crystal deposition as punctuate, linear densities within the articular cartilage (such as the knee meniscus) or joint capsules. Joint fluid examination shows the rhomboidal, weakly positive birefringent crystals of CPDD (see Fig. 116-2). As with gout, the patient's symptoms may mimic septic arthritis, and the two conditions can also occur simultaneously.

Management. There are no randomized trials to support any one therapy for a pseudogout attack. Therapy is complicated by the fact that calcium pyrophosphate crystals, once present, cannot be removed. NSAIDs are recommended but with the typical cautions related to gastrointestinal bleeding, renal impairment, and cardiovascular events. Guidelines recommend colchicines,[58] but at a lower dose than for gout: 0.5 mg three or four times a day, with or without a 1-mg loading dose. Intra-articular glucocorticoid injections have expert approval,[58] and a small nonrandomized trial supports a single intramuscular dose of betamethasone (7 mg) or intravenous dose of methylprednisolone (125 mg) over a multiday oral diclofenac regimen.[59] There is some evidence to support oral colchicine as prophylaxis for pseudogout; in a before-and-after trial of 10 patients with recurrent attacks, a dose of 0.6 mg twice daily during a year reduced the rate of new attacks.[60] Treatment of secondary metabolic causes of CPDD, although important, does not appear to influence the course of disease or frequency of acute flares of pseudogout.

Basic Calcium Phosphate Hydroxyapatite Crystal Disease

A variant form of crystalline disease results from basic calcium phosphate hydroxyapatite (BCP) deposits. BCP deposition in synovial fluid is more difficult to detect with light microscopy and is more rapidly progressive and destructive than pseudogout.[61] BCP arthropathy also is manifested with calcific tendinitis, calcific bursitis, and a "pseudopodagra" of the first MTP joint in young women. The Milwaukee shoulder syndrome is characterized by severe bilateral OA of the glenohumeral joint, rapid destruction of the rotator cuff, and BCP crystals, leading to joint instability and upward subluxation.[62] Treatment is often ineffective, but steroid injections and physical therapy provide some benefit.

Acute Calcific Periarthritis

Acute calcific periarthritis results when amorphous calcium hydroxyapatite deposits extravasate into periarticular soft tissue, causing a self-limited, crystal-induced inflammatory reaction.[61,62] It usually occurs in women and most commonly involves the hand or rotator cuff; the symptoms last less than a week, and the radiographic findings resolve after about 3 weeks.[63]

Trauma and Hemarthrosis

Trauma is a common cause of acute monarticular effusion. One prospective series of tense knee hemarthrosis presenting within 12 hours of injury identified complete or partial anterior cruciate ligament tears in 70% of patients and meniscal tears in 16%; synovial disruption was presumed responsible in 5%.[64] An older prospective series of 100 acute trauma patients with knee hemarthrosis in the United Kingdom found that despite normal radiographs and confirmation of hemarthrosis by aspiration, 99 patients had serious pathologic changes, such as anterior cruciate ligament, posterior cruciate ligament, or collateral ligament tears seen with prompt arthroscopy. In both studies, the authors recommended aspiration of a tense effusion and urgent arthroscopy.[65]

Monarticular Arthritis: Chronic

Osteoarthritis (Degenerative Joint Disease)

Principles of Disease. OA, or degenerative joint disease, is the most common form of arthritis among adults, especially in elders and patients who are overweight. As a tissue, cartilage has limited self-repair capability. Mechanical signaling mediates chondrocyte production of extracellular matrix molecules. Perturbations in loading (from trauma or excess weight), combined with biochemical and genetic factors, influence cytokine signaling and matrix composition, ultimately causing subchondral bone overgrowth, cartilage degradation, and synovial membrane inflammation.

Clinical Features. Patients with OA classically describe pain that worsens with activity and improves with rest. The lack of systemic symptoms also helps distinguish OA from RA. In the hands, osteophytic spurs (Bouchard's and Heberden's nodes in the PIP and DIP joints, respectively) may be palpated. The knee, so commonly involved, classically displays crepitus on active and passive ranging.

Radiographs classically show asymmetrical joint space narrowing, although the degree of narrowing often does not correlate with the patient's perception of pain. Radiographs may also show osteophyte formation at joint margins, subchondral cysts.

Synovial fluid is difficult to aspirate in OA but classically is noninflammatory, with fewer than 2000 cells/mm and few PMN cells.

Management. Many nonpharmacologic therapies for knee and hip OA have been endorsed through clinical guidelines and

www.ketabpezeshki.com 66485457-66963820

meta-analyses, such as weight loss, exercise, patient education, and wedge-soled shoes.[66] For the hand, orthotics and splints are also endorsed, although there are few supporting trials.[67]

For pharmacologic therapy, acetaminophen at 4 g/day is supported by a 2006 systematic review of 15 trials, showing superiority to placebo although inferiority to NSAIDs for the hip and knee.[68] However, because the adverse effects of acetaminophen are milder and less likely than with NSAIDs, acetaminophen is considered a first-line therapy in the European League Against Rheumatism (EULAR)[67] and American College of Rheumatology guidelines.[69]

Cyclooxygenase 2 inhibitors (e.g., celecoxib) are associated with less gastrointestinal bleeding risk than traditional NSAIDs in randomized trials, with the same apparent effectiveness.[70] However, subsequent concerns for increased cardiovascular toxicity have limited their use.

Opioid analgesics for OA pain are supported by a meta-analysis for pain reduction and functional improvement.[71] However, the meta-analysis reported that the substantial heterogeneity and attrition due to adverse effects of opioids compared with other agents and placebo limited the validity of the findings.

Therapies involving glucosamine and chondroitin have shown variable benefit. Newer network meta-analysis has revealed no clinically significant improvement with these drugs, alone or in combination, compared with placebo.[72]

Capsaicin is a low-toxicity topical agent that may help after a few weeks of therapy.[66] Intra-articular glucocorticoid injections, such as triamcinolone, have shown pain relief lasting months but uneven efficacy in various joints and no measurable effect on physical function.[67] The dose of triamcinolone is generally 10 mg for hand joints; 20 mg for elbows, ankles, and acromioclavicular joints; and 40 mg for knees, hips, and shoulders. Intra-articular hyaluronic acid injections have demonstrated some improvement in physical function and superior pain relief compared with intra-articular steroid injections (although apparent only after a period of many weeks to months).[73,74]

Management of OA in the ED is geared toward symptom relief; acetaminophen 4 g/day is supported by many reviews for safety and efficacy. NSAIDs and opioids may be superior to acetaminophen for particular kinds of OA but have more adverse effects. In patients resistant to these therapies, intra-articular injections of triamcinolone have demonstrated pain relief in the long term, depending on the joint, but with no impact on physical activities.

Emergency physicians should recommend proven nonpharmacologic therapies for knee and hip OA, such as weight loss, exercise, and wedge-soled shoes, with referral to an orthopedic surgeon for further management.

Polyarticular Arthritis: Acute

The differential diagnosis of polyarticular arthritis is much broader than that of monarticular arthritis (Fig. 116-6). Polyarticular arthritis presentations are classified as either acute (<6 weeks) or chronic (>6 weeks). The acute polyarticular presentations include gonococcal arthritis, viral arthritis (e.g., rubella, hepatitis), Lyme disease, reactive arthritis, and rheumatic fever. Chronic polyarticular presentations are caused by RA, systemic lupus erythematosus, scleroderma, psoriatic arthritis, dermatomyositis, and other autoimmune diseases. The diseases may also be distinguished on the basis of symmetrical or asymmetrical presentations. RA and systemic lupus erythematosus tend to be symmetrical, the others asymmetrical. The spondyloarthropathies (ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and the arthropathy of inflammatory bowel disease) involve predominantly larger joints, but psoriatic arthritis affects the small joints of the hands.

Viral arthritides have varied mechanisms of inflammation (Table 116-6) but typically are manifested as an acute, self-limited, nondestructive polyarticular arthritis.

Lyme Disease

Principles of Disease. *Borrelia burgdorferi* infection causes the multisystem disorder known as Lyme disease, the most common vector-borne illness in the Western world.[75] In the United States, endemic areas for *B. burgdorferi* and its vector tick *Ixodes* include the Northeast, the Upper Midwest, and northern California.[76] More than a quarter-million cases have been reported to the CDC since 1992, with approximately 25,000 cases per year in recent years.[75]

Clinical Features. Lyme disease follows a prescribed pattern of early disseminated disease (weeks to months after a tick bite) and late disease (from several months to years later). Musculoskeletal manifestations of the early stage primarily consist of migratory myalgias and arthralgias without objective evidence of actual arthritis or effusions.[77] Arthritis is the most common manifestation of late Lyme disease. When it is untreated, 50 to 60% of patients will have frank asymmetrical arthritis within 6 months, most commonly in large joints, particularly the knees (although recent series suggest a lower incidence of arthritis).[78] The natural history of Lyme arthritis is intermittent episodes that gradually abate in intensity and frequency during several years, even if it is untreated. Lyme arthritis appears to be autoimmune mediated rather than a direct result of the spirochetal infection, but early antibiotic therapy clearly reduces its incidence. Lyme arthritis seems to be more prevalent in infections in the United States because the endemic *B. burgdorferi* displays stronger arthritogenic properties than other strains.

Diagnostic Strategies. The history of a previous tick bite from an endemic area or the classic erythema migrans rash (although often not remembered by the patient) may aid the clinician in suspecting the diagnosis. Patients have minimal joint pain and usually are afebrile despite large joint effusions. The joint fluid is inflammatory with PMN cell predominance, but *Borrelia* cannot be cultured from it. The differential diagnosis includes gonococcal arthritis, septic arthritis, acute rheumatic fever, RA, and reactive arthritis. Routine blood testing is nonspecific and unhelpful. Confirmatory diagnosis is by immunoglobulin M and immunoglobulin G serologies.

Management. Prophylactic therapy after a tick bite is not generally recommended except for an *Ixodes* attachment of longer than 36 hours in an endemic region; a single doxycycline dose of 200 mg is then recommended by the Infectious Diseases Society of America (IDSA) clinical guidelines[78]; of note, these guidelines have led to an antitrust suit filed by disenfranchised physicians skeptical of the IDSA's statements on post-Lyme syndrome, although the evidence supporting the antibiotic regimens has not been criticized.[79] Lyme arthritis can generally be treated with a 4-week oral course of doxycycline, 100 mg twice daily. Doxycycline is preferred for its excellent oral absorption, low cost, and anti-inflammatory activity as a matrix metalloproteinase inhibitor. Amoxicillin 500 mg three times daily and cefuroxime axetil 500 mg twice daily are acceptable alternatives. Amoxicillin is used instead of doxycycline for pregnant and lactating women and for children younger than 8 years. If Lyme disease is diagnosed at the early stage of erythema migrans, only 2 weeks of treatment is recommended. More expensive intravenous regimens should be reserved for neurologic or cardiac Lyme disease or refractory Lyme arthritis. Antibiotic-refractory Lyme arthritis can be treated with an intravenous regimen or re-treated with an oral regimen of antibiotics, but these problem cases should generally be referred to an infectious disease specialist.

CLINICAL PATHWAY: MANAGEMENT OF THE PATIENT
WITH ACUTE POLYARTICULAR JOINT PAIN

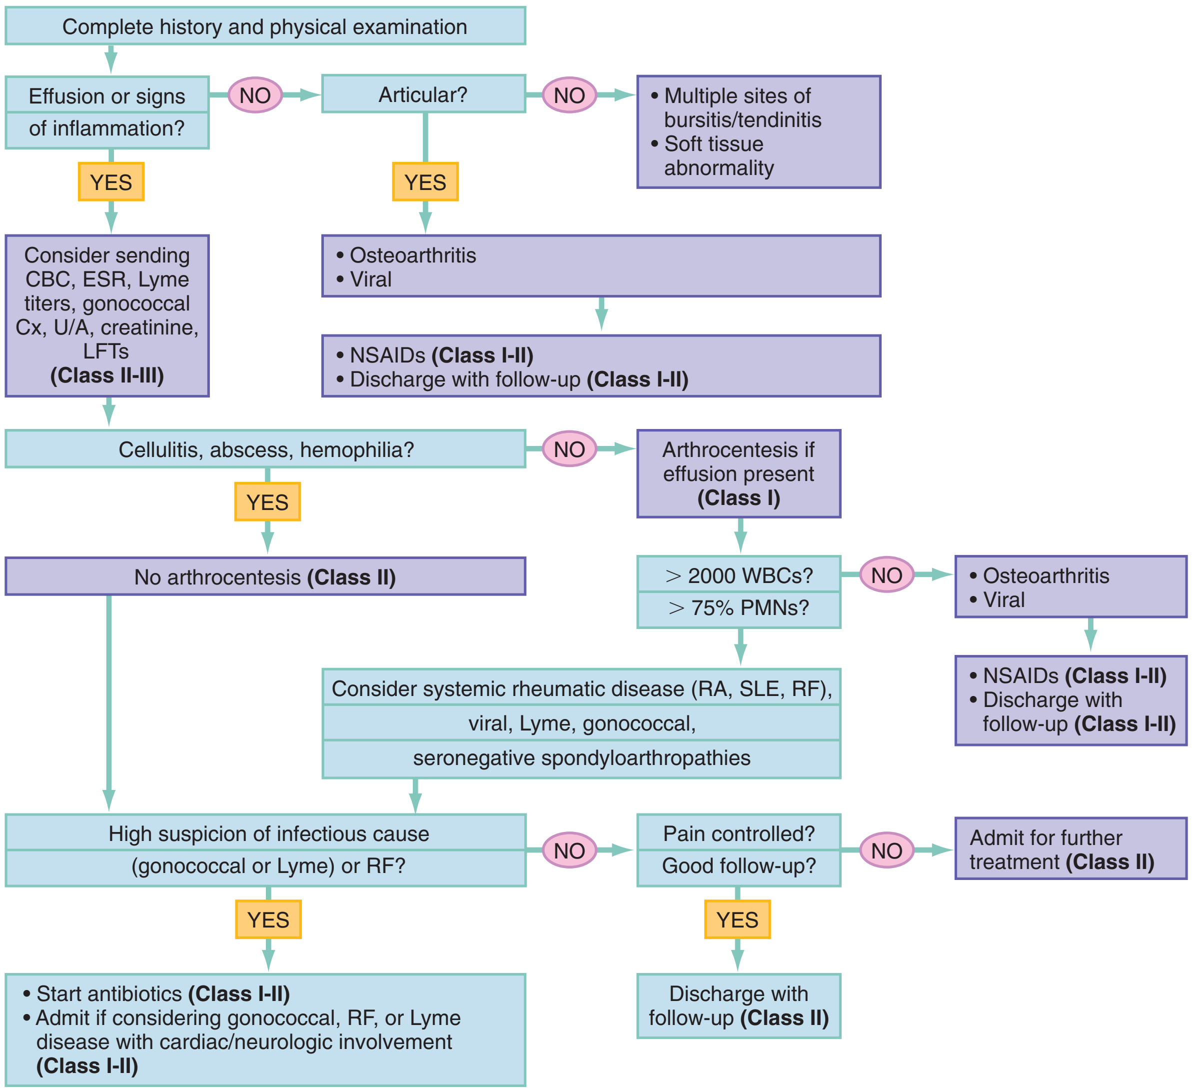

Figure 116-6. An initial approach to the patient with polyarticular joint symptoms. *CBC,* complete blood count; *Cx,* culture; *ESR,* erythrocyte sedimentation rate; *LFTs,* liver function tests; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PMNs,* polymorphonuclear cells; *RA,* rheumatoid arthritis; *RF,* rheumatic fever; *SLE,* systemic lupus erythematosus; *U/A,* urinalysis; *WBC,* white blood cell. (Modified from EB Practice LLC. 2004.)

Acute Rheumatic Fever

Principles of Disease. Acute rheumatic fever (ARF) is a systemic disease triggered by a complex hyperimmune response in the weeks after group A streptococcal (GAS) pharyngitis. Host cellular and humoral response to GAS infection attacks joint, cardiac, and other tissue, in part through molecular mimicry mechanisms. The incidence of ARF has dramatically declined in recent decades. This success is only partly due to the widespread use of antibiotics; improvements in social hygiene and transformation of GAS strains are probably more important factors.

Clinical Features. The clinical diagnosis of ARF is based on the Jones criteria. The presence of two major criteria (such as erythema marginatum; Fig. 116-7), or one major criterion and two minor criteria, with laboratory evidence of prior GAS infection is required (Box 116-3).

GAS infection–related arthritis, typically migratory, occurs in 75% of patients and mostly affects the large joints. The arthritis lasts 2 to 3 days in each joint and 2 to 3 weeks overall; the axial skeleton is spared. Joints appear modestly inflamed, but the pain is disproportionately excruciating to the patient. ARF arthritis responds so dramatically to salicylate or steroid therapy that the diagnosis can become clouded. Lack of response should promote an alternative diagnosis. Naproxen was shown to be as effective as aspirin and better tolerated in a randomized trial in children.[80]

Poststreptococcal reactive arthritis (PSRA) is another sterile GAS infection–related arthritis recently proposed for patients not fulfilling the Jones criteria for ARF.[81] The arthritis of PSRA tends to be more additive than migratory, with a lower extremity predominance. It typically responds less robustly to salicylates and persists longer than ARF, although a cohort of adults with poststreptococcal reactive arthritis, observed for many years, showed no increased risk of valvular heart disease compared with controls.[82]

Diagnostic Strategies. The diagnosis of ARF is largely clinical. Laboratory workup for suspected ARF is not conducive to ED care. Throat cultures are negative in 75% of patients with systemic manifestations of ARF.[82] Antibody titers to streptolysin O and anti-DNase B may demonstrate antecedent GAS infection.

Table 116-6 Characteristics of Viral Arthritides

VIRUS	ARTHRITIS PRESENTATION	SYMPTOM ETIOLOGY	DURATION OF SYMPTOMS	THERAPY
Hepatitis B	Mimics RA onset with symmetrical, migratory, or additive joint symptoms	Immune complex depositions in prodromal phase affect 10-25% of those with hepatitis B	Subsides with onset of jaundice	Supportive
Hepatitis C	Symmetrical RA-like mimic, or intermittent monarticular arthritis, often associated with salivary inflammation	Hepatitis C–induced mixed cryoglobulinemia	Variable, intermittent	Supportive; RA drugs are often helpful
Human immunodeficiency virus	Often monarticular arthritis, involving feet and ankles, potentially involving tendon, bursae, skin, and muscle inflammation as well	By virus itself or by reactive arthritis, drug-induced myopathy, immune reconstitution syndrome, or opportunistic septic arthritis	Variable	Driven by etiology
Parvovirus	The cause of fifth disease in childhood causes connective tissue syndrome in adults	Symmetrical stiffness in PIP joint, MP joint, without joint erosion	Self-limited, but may recur	Supportive
Rubella virus, rubella vaccine virus	Beyond classic maculopapular rash and lymphadenopathy, 30% of females and 6% of males with rubella show symptoms of arthritis	Virus grows well in synovial tissue, causing arthritis by direct infection	Symptoms appear within 2 weeks of vaccination or a week of rubella infection; self-limited	Supportive
Alphaviruses (Ross River, chikungunya, Mayaro)	Mosquito borne, often seen in epidemics after seasonal rains	Virus persists in synovial macrophages; symptoms arise from triggering of host response	Sometimes abrupt or insidious onset; symptoms can last 3-6 months; some patients have years of discomfort	Largely supportive; corticosteroids were once contraindicated but recently shown to be effective

MP, metacarpophalangeal; *PIP,* proximal interphalangeal; *RA,* rheumatoid arthritis.

Figure 116-7. Erythema marginatum in acute rheumatic fever. The pen mark shows the location of the rash approximately 60 minutes previously. (From Cohen J, Powderly WG: Infectious Diseases, 2nd ed. New York, Mosby/Elsevier, 2004.)

Box 116-3 Jones Criteria for Diagnosis of Acute Rheumatic Fever

Major Manifestations
- Polyarthritis
- Carditis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

Minor Manifestations
- Clinical findings
  - Arthralgia
  - Fever
- Laboratory findings
  - Elevated acute-phase reactants: erythrocyte sedimentation rate, C-reactive protein
- Prolonged PR interval on electrocardiography

Plus supporting evidence of prior group A streptococcal infection (elevated or increasing streptococcal antibody titer, positive rapid streptococcal test or bacterial throat culture results, recent scarlet fever)

From Guidelines for the diagnosis of rheumatic fever. Jones criteria, 1992 update. Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. JAMA 268:2069, 1992.

Synovial fluid is inflammatory in nature and sterile, with a WBC count ranging between 10,000/mm^3 and 100,000/mm^3, a protein level of approximately 4 g/dL, no crystals, and a negative culture.

Management. Successful management of ARF requires three things: rapid eradication of the GAS infection; prophylaxis against recurrent infection; and acute treatment of arthritis, carditis, and chorea. The current recommended treatment of suspected acute GAS infection is benzathine penicillin 0.6 to 1.2 million units intramuscularly or 10 days of oral penicillin (or erythromycin if the patient is penicillin allergic). Long-term prophylactic treatment to prevent recurrences of ARF is provided with either oral or parenteral penicillin or erythromycin. The duration of prophylaxis depends on the age of the patient, the presence of cardiac involvement, the number of previous attacks, and other factors.

Other than antibiotics, ARF treatments were developed well before the era of randomized trials, so their evidentiary basis is suboptimal. High-dose aspirin (50-100 mg/kg/day in four daily doses) for 2 to 4 weeks improves the arthritis and fever but not the symptoms of carditis.[83] Smaller studies have suggested a benefit to oral or intramuscular hydrocortisone over aspirin if carditis is present (1-2 mg/kg/day, slowly tapered during 2-4 weeks).[83,84]

Polyarthritis: Chronic

Rheumatoid Arthritis

Principles of Disease. Although RA is usually considered a chronic and insidious disease, at least 20% of patients have an acute

www.ketabpezeshki.com 66485457-66963820

presentation.[85] RA develops in women two to three times more often than in men, with a peak incidence between the fourth and fifth decades of life. Prevalence is between 0.5 and 1% of Western populations and 5% of women by 70 years of age.[85] There appears to be a genetic predisposition related to the HLA-DR4 haplotype. Immune complexes are formed that stimulate PMN cells to release the enzymes that ultimately cause joint destruction. The synovial cells increase dramatically in number and produce even more inflammatory substances. A pannus of granulation tissue is formed that ultimately destroys the joint.

Clinical Features. Patients commonly see a physician after a prodromal period of fatigue, weakness, and musculoskeletal pain that may last weeks to months. Fever and weight loss may be present. The patient's joints begin to swell in a symmetrical and additive pattern, particularly the hands (MP and PIP joints), wrists, and elbows. The foot may be the initial site of involvement and is affected in more than 90% of patients with RA, particularly the great and little toe MTP joints. Classically, patients describe morning stiffness lasting more than an hour. DIP joints of the fingers are not involved, which helps distinguish RA from OA, reactive arthritis, and psoriatic arthritis.[85]

Acute presentations may have only warm, tender, swollen joints that may be difficult to distinguish from a viral arthropathy. Tenosynovitis can occur with acute RA. Acute pericarditis is not related to the duration of disease and also may be an early presentation.

Long-standing changes of RA include MP and PIP joint swelling, ulnar deviation, swan-neck and boutonnière deformities of the hands, and limitation of dorsiflexion of the wrist. The knee is often affected, in the short term with effusion and in the long term with muscle atrophy and Baker's cysts. Bursae in the retrocalcaneal region are common complications. Extra-articular complications are seen in half of patients with RA and include subcutaneous nodules (associated with more severe disease), vasculitis of the skin, pulmonary fibrosis, mononeuritis multiplex, and Sjögren's and Felty's syndromes. Long-standing RA is associated with atlantoaxial subluxation as well as with laryngeal deviation, requiring anticipation before endotracheal intubation.

Diagnostic Strategies. The emergency workup of the patient with suspected RA is directed at exclusion of other causes of arthritis, particularly septic arthritis. However, the definitive diagnosis of RA is complicated and involves confirmatory serology and a chronicity of 6 weeks or more.[86] ESR and CRP levels may be elevated but are nonspecific and often elevated in other rheumatologic diseases. Rheumatoid factor, an antibody against gamma globulin, is eventually present in approximately 75 to 85% of patients with RA, although it is present in only 50% in the first 6 months.[85]

Early radiographic features of RA are soft tissue swelling and juxta-articular osteoporosis leading to uniform joint space narrowing (Fig. 116-8). Subluxation with loss of joint alignment is a later finding.

Synovial fluid analysis is helpful to rule out infectious or crystalline processes. Arthrocentesis reveals inflammatory fluid with WBC counts between 4000 and 50,000/mm^3 and more PMN cells (75%) than are usually seen with crystal disease.

Management. Excessive movement increases inflammation, so the initial treatment is rest in combination with anti-inflammatory medication.[87] For early mild disease, many clinicians often still use the salicylates or other NSAIDs, which have gastrointestinal and renal toxicities related to their inhibition of cyclooxygenase. Oral prednisone, 5 to 15 mg daily, can effectively control mild inflammation as a bridge to more advanced therapy in early disease.

Because the early months are critical in preventing major joint damage, particularly in moderate to severe disease, the use of disease-modifying antirheumatic drugs (DMARDs) has become extensive and is now recommended by the American College of Rheumatology.[88] Clinical studies support the efficacy of a combination of methotrexate and a tumor necrosis factor blocker in reducing early disease activity. DMARDs are typically prescribed by the consulting rheumatologist, but emergency physicians should be familiar with their potentially life-threatening complications (Table 116-7).

Figure 116-8. Rheumatoid arthritis of the wrist, with osseous erosions shown here including triquetrum, pisiform, scaphoid, and radius. There also are erosions at the ulnar aspect of the distal radius and the ulnar styloid process secondary to involvement of the inferior radioulnar compartment. Diffuse cartilage loss also is evident in the radiocarpal compartment. (From Firestein GS: Kelley's Textbook of Rheumatology, 8th ed. Philadelphia, WB Saunders, 2008.)

Alternatives to DMARDs include combinations of sulfasalazine 1000 mg two or three times daily and hydroxychloroquine 200 to 400 mg/day. NSAIDs (such as ibuprofen 3200 mg daily) are also commonly prescribed. A systematic review concluded that short-term, low-dose steroids (15 mg/day) are significantly more effective than NSAIDs (and placebo) for alleviation of RA symptoms.[89]

Intra-articular glucocorticoid injections have been studied, but often with agents[90] (rimexolone 40 mg) or in regimens (multiple doses of intra-articular betamethasone in conjunction with methotrexate) that are not applicable to emergency medicine practice. A single dose of intra-articular triamcinolone 60 mg (with 2% lidocaine) was shown to be superior to intramuscular triamcinolone (also with lidocaine) in patients with known RA of the knee,[91] but the first baseline evaluation was 1 week after injection.

A systematic review showed no evidence to support the use of resting wrist and hand splints to improve function, symptoms, or quality of life, although patients did prefer the use of splints to nonuse. Extra-depth in-soled shoes were shown to improve walking and pain during several months.[92]

RA management has progressed in recent years, and early use of DMARDs is recommended in moderate to severe disease to prevent joint damage. These drugs are generally best prescribed by rheumatologists or the primary care physician who will be caring for the patient. Emergency physicians should recommend prompt rheumatology follow-up and bridge care by prescribing NSAIDs such as ibuprofen 3200 mg daily as a first-line therapy or, for patients who cannot tolerate NSAIDs, prednisone 15 mg/day.

www.ketabpezeshki.com 66485457-66963820

Table 116-7 Toxicity of Rheumatoid Arthritis Drugs

DRUG	CLASS	MAJOR TOXICITY	PEARL
Methotrexate	Conventional DMARD	Hepatic, bone marrow, lung	Pulse therapy less toxic than daily
Hydroxychloroquine	Antimalarial	Retinal	
Gold salts	Conventional DMARD	Bone marrow	Uncommonly used now
Anakinra	Anti–IL-1	Pneumonia, serious infections, leukopenia	Higher risk in patients with asthma
Abatacept	T-cell modulator		Avoid in COPD
Leflunomide	Pyrimidine antagonist	Diarrhea	Very long half-life
Etanercept	Anti-TNF	Sepsis, pneumonia, tuberculosis	
Infliximab	Anti-TNF	Sepsis, pneumonia, tuberculosis	
Adalimumab	Anti-TNF	Sepsis, pneumonia, tuberculosis	
Rituximab	Anti-CD20 of B-cell lymphocytes	Fatal infusion reactions	Multiple organ collapse typically with first infusion

COPD, chronic obstructive pulmonary disease; *DMARD,* disease-modifying antirheumatic drug; *IL-1,* interleukin-1; *TNF,* tumor necrosis factor.

Intra-articular steroid injections are an option for patients with just one or two joints involved. Splints, joint rest, and supportive care have a role as well.

Adult-Onset Still's Disease

Adult-onset Still's disease (AOSD) is a rare multisystem inflammatory disorder characterized by acute arthritis, characteristic rash, and quotidian or double-quotidian fevers (with the highest temperatures seen in the late afternoon or early evening). The rash is a salmon-colored macular evanescent rash that occurs only with the fever. The protean manifestations of AOSD include sore throat, myalgias, splenomegaly, hepatitis, and pericarditis. The differential diagnosis includes other acute arthritides (especially rheumatic fever) and other causes of "fever of unknown origin." Acute treatment options for AOSD include aspirin, NSAIDs, low-dose corticosteroids, and intravenous immune globulin.[93]

Relapsing Polychondritis

Relapsing polychondritis, a rare multisystem disorder of unknown etiology, is manifested with recurrent severe inflammation of joints, sclera, ears, nose, and vessels of the heart and kidneys. Most patients eventually have unilateral or bilateral external ear swelling and redness. Because of the rarity of this disorder, there are no controlled trials of therapies. In some series, flare-ups are self-limited and well managed with NSAIDs or colchicines (0.6 mg twice daily). However, tracheobronchial cartilage inflammation is possible and can be precipitous, causing respiratory distress and airway compromise. For this, pulse-dose steroids (1 g/day), racemic epinephrine, and sometimes stenting are recommended.[94]

Seronegative Spondyloarthropathies

The seronegative spondyloarthropathies share the characteristics of sacroiliac involvement, peripheral inflammatory arthropathy, absence of rheumatoid factor, pathologic changes around the enthesis (ligamentous and tendinous insertion into bone), and a genetic component related to the HLA-B27 marker. The most important of these chronic polyarthritic inflammatory diseases are ankylosing spondylitis, reactive arthritis, the arthropathy of inflammatory bowel disease (enteropathic arthritis), and psoriatic arthritis. Whereas some clinical overlap exists, each has its distinctive features.

Ankylosing Spondylitis

Clinical Features. Patients with ankylosing spondylitis generally have back discomfort with radiologic evidence of sacroiliitis. There is a male predominance. The classic presentation is chronic, insidious back discomfort of more than 3 months' duration, with morning stiffness that improves with exercise, in someone younger than 40 years. Uveitis is the most common extra-articular manifestation, but life-threatening aortic root disease can rarely occur. The peripheral joints are involved in up to 30% of patients with enthesopathic involvement, such as plantar fasciitis and Achilles tendinitis. On radiologic examination, there is a symmetrical squaring of the margins of the vertebral bodies and later the development of a "bamboo spine." MRI changes occur even earlier at the sacroiliac joint.

Management. The goals of therapy are to control pain, to decrease inflammation, and to begin physiotherapy and strengthening exercises. Recent literature review and consensus with use of Delphi methodology recommend a trial of at least two NSAIDs for symptomatic patients.[95] Anti–tumor necrosis factor, sulfasalazine, methotrexate, and monoclonal antibodies are also options for more severe disability and pain.

Reactive Arthritis (Formerly Reiter's Syndrome)

Clinical Features. Reactive arthritis occurs in genetically susceptible hosts after infection with *Chlamydia trachomatis* in the genitourinary tract or *Salmonella, Shigella, Yersinia,* or *Campylobacter* organisms in the gastrointestinal tract. A number of other microorganisms have also been postulated as causative agents.

Reactive arthritis is generally a disease of patients aged 20 to 40 years, in whom arthritis develops 2 to 6 weeks after an episode of urethritis or dysentery. Because cervicitis is often asymptomatic, the diagnosis is more of a problem in women. The syndrome is predominantly polyarticular and asymmetrical and often additive (Fig. 116-9). The weight-bearing joints of the lower extremities are commonly involved: knees, ankles, and feet, particularly the heels ("lover's heel"; Fig. 116-9B). Other physical signs appear early and may be gone when the musculoskeletal complaints persist. Patients may have conjunctivitis early in the disease, which may progress to uveitis. Up to 10% of patients have initially painless lesions of the oral mucosa and tongue that later develop into shallow painful ulcers.[96] Similar lesions are seen on the glans penis (balanitis circinata), particularly in uncircumcised men (20% of patients). The penile lesions in circumcised men are more psoriatic in appearance. Fingers and toes may swell and appear sausage-like, a phenomenon that also occurs in psoriatic arthritis. In 10% of patients, hyperkeratotic lesions of keratoderma blennorrhagica

www.ketabpezeshki.com 66485457-66963820

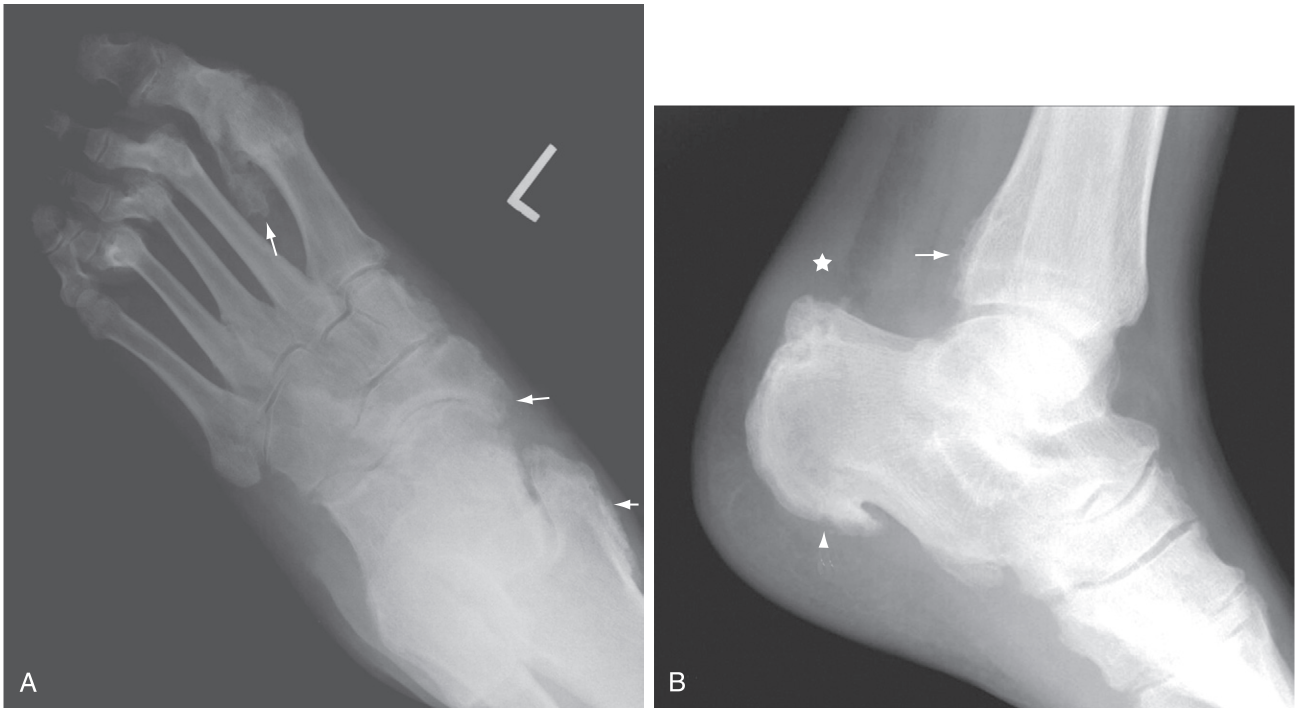

Figure 116-9. Radiographic findings of the foot in reactive arthritis. **A,** Anteroposterior view of the foot reveals erosions and bone proliferation of the first through fourth metatarsophalangeal joints with subluxation. Fluffy bone proliferation is noted along the medial malleolus, midfoot, and sesamoid bones of the first metatarsal head (*arrows*). **B,** Lateral view of the hindfoot shows ill-defined plantar calcaneal enthesophytes (*arrowhead*), periosteal new bone formation along the posterior aspect of the distal tibia (*arrow*), retrocalcaneal bursitis and thickening of the Achilles tendon (*star*), and erosions at the subjacent calcaneus. (From Firestein GS: Kelley's Textbook of Rheumatology, 8th ed. Philadelphia, WB Saunders, 2008.)

(waxy plaques) develop on the palms and soles and look like pustular psoriasis. Patients may have inflammation at the insertion of the Achilles tendon, and up to one third of patients have iliac crest, ischial tuberosity, and sacroiliac joint inflammation, with limitation of vertebral movement on range of motion.

Synovial fluid is inflammatory in nature with a predominance of PMN cells. *Chlamydia, Salmonella,* and *Yersinia* antigens have been found in the synovial membrane and even in the joint fluid, but cultures are sterile. Early x-ray films show an enthesitis where ligaments attach to bone that occurs at the sacroiliac joints, ischial tuberosities, greater trochanter, and Achilles insertion. Patients may have a single episode (the mean length of an episode is 4-7 months) or recurrent episodes of arthritis or a continuous spectrum of disease generally involving the ankles and calcaneus.

Management. Patients with reactive arthritis respond well to NSAIDs, particularly indomethacin, up to 200 mg/day. Antibiotics improve recovery time for patients with *Chlamydia*-triggered reactive arthritis; no benefit has been found for arthritis with a gastrointestinal cause.[96]

Enteropathic Arthritis. Roughly 10 to 22% of patients with inflammatory bowel disease have acute migratory, inflammatory polyarthritis of the peripheral joints, especially the knees. Associated inflammatory sacroiliitis and spondylitis are more common in men. The peripheral arthritis generally correlates with flare-ups of the bowel disease, but the spinal manifestations do not. NSAIDs are first-line therapy for axial and peripheral joint inflammation, although they may exacerbate inflammatory bowel disease. Sulfasalazine and intra-articular glucocorticoid injections are also options for peripheral arthritis.

Psoriatic Arthritis. Psoriatic arthropathy occurs in up to 20% of patients with psoriasis. Several forms exist: asymmetrical oligoarthropathy (with sausage digits), symmetrical polyarthropathy, spondylitis (asymmetrical as in reactive arthritis), DIP joint involvement, and arthritis mutilans (Fig. 116-10).[97] Whereas NSAIDs are considered a cornerstone of therapy, few trials have been performed on psoriatic arthritis; instead, support is derived from trials involving RA, OA, and ankylosing spondylitis. Therapies like sulfasalazine at 2 g/day have shown benefit in large trials, but the duration of therapy (36 weeks) necessitates involvement of a rheumatologist.

Fibromyalgia

Clinical Features. Patients with fibromyalgia commonly present to the ED with diffuse musculoskeletal pain. The encounter is typically difficult for both the patient and the physician because the disease is ill-defined, there may be suspicion of analgesic abuse, and psychiatric comorbidity is common. Current thinking about the pathophysiologic mechanism of this disorder hypothesizes that the patients process normal pain stimuli aberrantly.[98] Patients with fibromyalgia have a history of long-standing, idiopathic, widespread pain (bilateral, upper and lower body, and spine) and an examination showing excessive tenderness of 11 of 18 specific muscle-tendon sites. The differential diagnosis includes the other rheumatic diseases, hypothyroidism, and depression, and more extensive evaluation should be considered with symptoms of short duration. Fibromyalgia is not consistent with the presence of synovitis, fever, or neurologic deficits. Care should be taken before a diagnosis of fibromyalgia is made; many patients are seeking only a reassurance that no emergency condition is present.

Management. Treatment of fibromyalgia in the ED includes ruling out of associated disease, relief of acute pain with anti-inflammatory medications, provision of empathy and education, and referral of the patient to a provider experienced in chronic pain management. For patients in significant distress, the combination of tramadol 75 mg four times daily with acetaminophen

www.ketabpezeshki.com 66485457-66963820

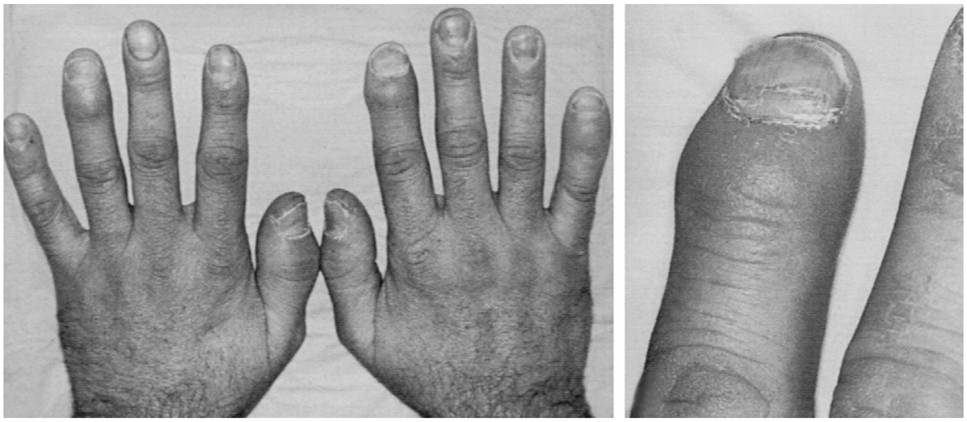

Figure 116-10. Psoriatic arthritis. Note the asymmetry of the distal interphalangeal joint involvement and the associated psoriatic nail disease. (From Firestein GS: Kelley's Textbook of Rheumatology, 8th ed. Philadelphia, WB Saunders, 2008.)

has been shown to be effective.[99] Selective serotonin reuptake inhibitors, low-dose tricyclic antidepressants, and pregabalin have also been shown to improve pain measures and sleep in patients with fibromyalgia.[100]

Polymyalgia Rheumatica

Polymyalgia rheumatica is manifested with musculoskeletal aching and morning stiffness of several weeks' duration, especially of the shoulder and pelvic girdle, almost always in persons older than 50 years.

Physical signs are modest. An elevated ESR can be used to screen for an inflammatory arthritis; a value above 100 mm/hr by Westergren method is thought to be clinically significant, and values below 50 mm/hr make polymyalgia rheumatica unlikely.[101] However, ESR also rises with age and is elevated in infection and paraneoplastic states as well as in pregnancy and hypercholesterolemia. Congestive heart failure and sickle cell disease lower ESR. CRP is an acute-phase protein that can increase within 4 to 6 hours, given sufficient stimulus, with a half-life of 18 hours on resolution of the acute phase. The basal CRP level also rises with age as well as with body mass index. Values above 10 mg/L are indicative of clinically significant inflammation, although scleroderma, polymyositis, and dermatomyositis are not accompanied by CRP elevation.

The disease course is usually self-limited, and most patients will respond to low-dose prednisone (20 mg/day or less). All patients should be referred for evaluation for progression to giant cell arteritis, a closely related disorder.

Scleroderma (Systemic Sclerosis)

Scleroderma has many manifestations discussed in other chapters; musculoskeletal manifestations of scleroderma include morning joint stiffness, tendon friction rubs, symmetrical arthralgias and arthritis, sclerodactyly, and Raynaud's phenomenon. The arthritis seems generally responsive to anti-inflammatory treatment, although cyclophosphamide is the only agent with benefit seen in randomized trials. Scleroderma renal crisis is a feared emergent complication, so screening for renal failure is important, and early use of angiotensin-converting enzyme inhibitors has improved long-term outcomes.

DISPOSITION

Whereas the majority of emergency presentations for arthritis can be followed up satisfactorily in the outpatient setting, the challenge for emergency physicians evaluating acute arthritis is to determine which presentations are rapidly progressive and potentially disabling. Most important, the possibility of septic arthritis must be considered and excluded.

Patients diagnosed with nongonococcal septic arthritis, on the basis of a positive result of Gram's stain or culture or a strong clinical suspicion in the face of a negative Gram's stain result, are admitted for parenteral antibiotics and evaluation for possible arthroscopy or arthrotomy. Patients in whom a disseminated gonococcal infection is suspected are admitted for parenteral antibiotics and orthopedic consultation, except in cases in which the patient is well appearing, the symptoms are mild, and the patient is able to comply with the daily follow-up plans. Patients with noninfectious causes of arthritis can be discharged, assuming their pain is controlled and appropriate follow-up can be arranged.

KEY CONCEPTS

- The most likely cause of emergency arthritis presentations can usually be identified by considering the number of joints involved (monarticular vs. polyarticular), the distribution of joint involvement (large vs. small joints and symmetrical vs. asymmetrical joint involvement), and the time course (a duration of 6 weeks helps differentiate acute arthritides from chronic).
- Consider the possibility of septic arthritis in all patients who present with acute monarticular arthritis.
- There is no combination of examination findings or blood tests that places septic arthritis below the threshold for performance of arthrocentesis in patients presenting with new, hot, swollen joint pain. Synovial fluid analysis is necessary to establish or to rule out the diagnosis of septic arthritis, and delays in treatment worsen outcomes.
- The presence of crystals in synovial fluid or a negative Gram's stain result does not completely eliminate the possibility of septic arthritis. Bacterial arthritis can coexist with gout or pseudogout, and the result of Gram's stain is positive in only 50 to 80% of cases of septic arthritis.
- Many other common arthritides, such as gout, rheumatoid arthritis, and osteoarthritis, can be managed with NSAIDs as a first-line therapy. In those who cannot tolerate or have not improved with NSAIDs, systemic or intra-articular steroid therapy has varying levels of support. Appropriate follow-up is crucial for prophylaxis against future flare-ups.

Chapter 117

Tendinopathy and Bursitis

Michael J. Schmidt and Stephen L. Adams

TENDINOPATHY

Perspective

Emergency physicians may see a wide variety of patients with tendinopathies due to overuse and injury given the increased participation of people in athletics and fitness.[1] Approximately half of all sports participants will be injured at some time, and of these injuries, up to half will involve a tendinopathy. Tendinopathies have been implicated in approximately 40% of tennis injuries, and between 37 and 79% of participants in running will suffer an injury, with most of these injuries related to overuse.[1,2] In the workplace, the incidence of work-related musculoskeletal disorders is higher in occupations that involve repetitive motion, localized contact stress, awkward positions, vibrations, and forceful exertion. Ergonomic and medical intervention programs may reduce the incidence of work-related injuries.[3]

Complicating the acute pain and functional limitations, tendinopathies often become chronic and can be disabling. Patients may have symptoms for extended periods despite appropriate therapy. The management of tendinopathy focuses on identification of the cause of discomfort; elimination of sources of primary tendinopathy; institution of treatment modalities, such as analgesic medication, protection, relative rest, application of ice, compression, and elevation as necessary; modification of behavior to minimize or to eliminate sources of continuing irritation; and, importantly, referral for appropriate follow-up care and early rehabilitation.[4,5]

Principles of Disease

Tendons are collagenous structures that connect muscle to bone. They transmit the forces originating in the muscle to the bone, which enables joint motion. The diagnosis of *tendinitis,* a commonly used term implying an "inflammation of the tendon," has long been attached to many overuse injuries. Many practitioners now advocate use of the term *tendinosis* as a more accurate reflection of the pathologic process, given that histologic findings consistent with inflammation are not clearly evident in pathoanatomic studies. Although it has been noted that reliable, well-conducted epidemiologic studies have not been performed for most tendinopathies, the histopathologic substratum, in many cases, is degenerative.[1] The term *tendinopathy* is used throughout this chapter to refer to the impaired tendon, as it encompasses the variety of pathologic processes.

Mechanical overload and repetitive microtrauma to the musculotendinous unit are thought to be the major precipitating causes of most tendinopathies. This is a result of extrinsic and intrinsic factors that modify the pathophysiologic state. Intrinsic factors, such as age, gender, malalignment, joint laxity, muscle weakness, and imbalance, can result in excessively high or frequent mechanical loads during normal activity. Extrinsic factors, such as ergonomics, abnormal movements, excessive duration of activity, and increased frequency or intensity of activity, can also contribute to the development of a tendinopathy. Many injuries have a multifactorial origin.[6] An increased incidence of tendinopathy and tendon rupture, particularly of the Achilles tendon, is reported in patients taking fluoroquinolone antibiotics, particularly in individuals receiving steroid treatment or those with renal disease.[7]

Under optimal conditions, such as appropriate athletic training, the musculotendinous units are able to adapt to tension overload because of the ability of bone to increase its load-bearing capacity and because of an increase in size and strength by hypertrophy of existing muscle fibers. An enhancement of tendon and ligament strength occurs by an increase in collagen content, collagen cross-linking, and mucopolysaccharide content. Unfortunately, many athletes may not allot sufficient time for this adaptive process to occur. For instance, a runner may increase mileage, intensity, or both with excessive alacrity, not allowing time for the cellular changes that are required to adapt to the increased stresses. Poor technique and improper equipment may also contribute to the development of an overuse syndrome.

The pathophysiologic mechanism of tendon healing has mainly been described in the literature in the context of acute injury (e.g., rupture), and correlation to the healing process in tendinopathies remains unclear. Acutely injured tendons go through several stages in the healing process, and it may take 6 to 12 weeks for structural organization and collagen cross-linking to return the tendon to its preinjured strength.[8] As the healing process ensues, unrestricted activity is generally avoided. However, atrophy associated with immobilization should also be avoided because the strength in healing tendons and ligaments increases faster when controlled forces are applied. Consequently, flexibility forces, eccentric strength training, and a measured return to resistive exercises have been suggested as long as pain is not produced. Most patients with overuse tendinopathies fully recover within 3 to 6 months.[9] In summary, a prescription for good follow-up with proper rehabilitation is important in caring for the patient with tendinopathy. Some areas with common presentations of tendinopathies are diagrammed in Figure 117-1.

Clinical Features

General Tendinopathy

The history of the patient presenting with a tendinopathy can be variable, although certain clinical aspects are characteristic. A

www.ketabpezeshki.com 66485457-66963820

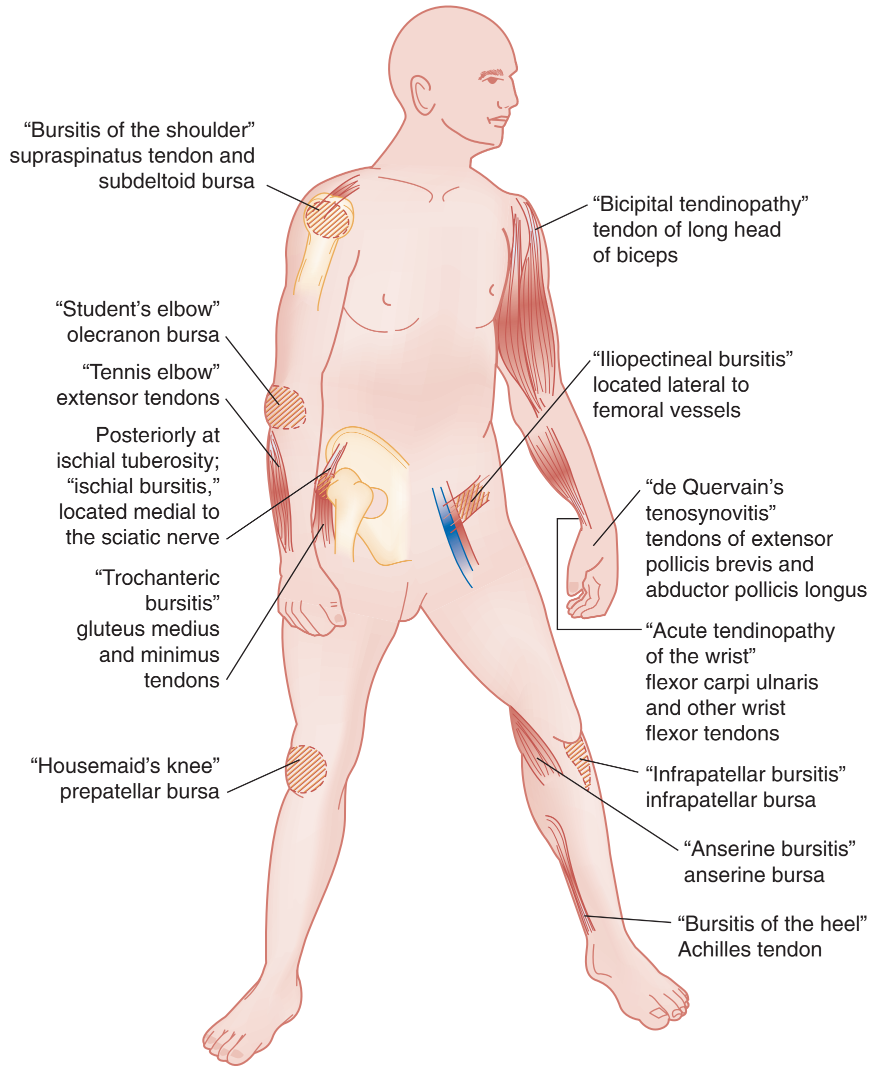

Figure 117-1. Location of common sites for tendinopathy or bursitis. (Modified from Branch WT: Office Practice of Medicine, 2nd ed. Philadelphia, WB Saunders, 1987.)

recent history of repetitive stress may be obtained by inquiring about changes in sports or other recreational activities, work activities, or changes in the workplace. Many patients initially report no such changes, but when they are prompted to consider activities during several weeks or months (including sports equipment used, workplace ergonomic features, protective boots, or other features), a potential inciting change or activity may be elicited. On occasion, no cause is identified for an inciting mechanical overload. A history of fluoroquinolone therapy, infectious disease, or other systemic illness should also be obtained as initial presentations of rheumatologic disorders or infections, such as those from *Mycobacterium,* have been described.[7,10-12]

Pain is the most common symptom of the patient who presents with tendinopathy. Increasing discomfort, nonradiating, at the site of the affected tendon is a general symptom.[4] The discomfort is frequently described as more severe subsequent to periods of rest. Unlike the discomfort of morning stiffness associated with arthritis, the pain of tendinopathy may resolve after initial movement, only to be manifested as a throbbing pain after completion of exercise. The patient may have had prior similar episodes. Continued episodes may be accompanied by an increased severity in pain. Consequently, it may be helpful to know whether a diagnosis was made (and how) and which treatment rendered (if any) was successful.

In the evaluation of the patient with a tendinopathy, a thorough, directed musculoskeletal examination yields important information. Inspection searching for signs of edema, effusion, erythema, atrophy, deformity, symmetry, or trauma can be helpful. Palpation of the tendon, noting warmth or evidence of crepitation on movement, is important. Evidence of tenderness over the tendon, especially localized, reproducing the patient's pain should be elicited.[4] Underlying bone tenderness (and consideration of other differential diagnoses, including avulsion fracture and osteomyelitis) should be assessed as well. Motor function, particularly passive and active range of motion (and symptoms elicited during the examination), strength (and evidence of weakness or pain), and joint involvement and stability should be noted.

In narrowing the diagnosis, it is important to determine whether the source of pain is articular (within the joint capsule) or periarticular (around the joint capsule). In general, arthritis produces generalized joint pain, warmth, swelling, and tenderness. The discomfort of arthritis increases with both passive and active motion of the joint. In contrast, the pain of a tendinopathy tends to be more localized.[4] Tenderness and swelling do not occur uniformly across the joint, and pain may be produced only with certain movements, most commonly with resisted active contraction or passive stretching of the affected muscles or tendons.

Specific Tendinopathies

Shoulder. Tendinopathies of the shoulder joint include impingement syndrome, which includes subacromial bursitis or rotator cuff tendinopathy, bicipital tendinopathy, calcific tendinopathy, and adhesive capsulitis.

Impingement Syndrome and Rotator Cuff Tendinopathies. The shoulder joint is predisposed to soft tissue injury because of its extensive range of motion and unique anatomic structure. Although it is inherently unstable, the muscles of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis) and the glenohumeral ligaments serve to stabilize the joint. The muscles of the rotator cuff originate from the scapula (hence their nomenclature), and their tendinous insertion is found on the fibrous capsule of the glenohumeral joint after traversing through the subacromial space. The presence of the subacromial bursa, as for all bursae, serves to ensure fluidity of movement, but it may become inflamed as a part of an impingement syndrome.[13] Impingement of the tendons occurs because of their unique position interposed between the humeral head and the acromion, which may predispose to a chronic tendinopathy. The functional arc of the elevated shoulder is forward and in the anterior plane. As a result of this position, the greater tuberosity of the humerus may compress (impinge) the tendons of the rotator cuff (usually the supraspinatus) against the undersurface of the anterior third of the acromion. Because of the insertion of the tendon of the long head of the biceps, it too may be involved as part of the impingement syndrome.[13] Development of this tendinopathy may be a result of overuse of the extremity that leads to microtrauma of the tendinous fibers, or it may be due to individual anatomic differences (congenital or from the process of aging, such as osteophytic changes) that predispose to tendinopathy, or both. Other entities that may coexist and complicate an impingement syndrome include subacromial bursitis, bicipital tendinopathy, and calcific tendinopathy.[14]

More than 30 years ago, Neer noted that 95% of rotator cuff tears are associated with impingement (excluding tears due to a one-time traumatic event). He described three progressive stages of the impingement syndrome as a result of overuse.[15] The first stage is frequently seen in athletes younger than 25 years who participate in sports that require repetitive overhead motions of the shoulder (e.g., swimming and baseball).[15,16] It is characterized by edema and hemorrhage within and around the tendon. The pain is usually described as a dull ache over the anterolateral shoulder, extending from the shoulder to the middle upper arm, often occurring after an activity involving flexion and abduction of the arm. Point tenderness may be elicited over the greater tuberosity. No weakness or loss of motion is generally present. This condition is generally believed to be reversible with appropriate treatment. In the second stage, as mechanical trauma continues, fibrosis and thickening of the tendon and subacromial bursa can occur. This generally affects patients between 25 and 40 years of age. The pain becomes constant and may worsen at night. Active motion may be limited by pain, and any activity involving overhead movement exacerbates the symptoms. Passive range of motion should be preserved, and on physical examination, pain is more diffuse and intense. The third stage has symptoms similar to those of the second stage but may involve a prolonged history of shoulder problems. The range of motion of the shoulder is usually decreased because of either disuse or a partial rotator cuff tear. On pathologic examination, tendon degeneration and attrition may be present. Partial-thickness tears may occur or extend with minor trauma or stress. Complete tears of the rotator cuff, biceps tendon rupture, and osteophytic bone changes are sometimes seen.

Physical examination in the evaluation of a rotator cuff tendinopathy includes maneuvers that can exacerbate the symptoms of impingement.[17] Because the supraspinatus tendon is most often involved, a physical examination sign (sometimes referred to as *Jobe's sign,* after Frank Jobe, team physician of the Los Angeles Dodgers, or the *empty can test,* describing the position of emptying aluminum cans) is helpful in assessing the supraspinatus tendon with resistance testing. With the arms abducted at 90 degrees in the scapular plane (30 degrees anterior to the coronal plane), the arms are internally rotated with the thumbs pointed downward. The examiner places a downward force on the arms, and the patient is instructed to resist the examiner and to keep the arms parallel to the floor. Weakness or pain is considered a positive finding. If the patient is unable to resist the force of the examiner, supraspinatus weakness should be suspected.

Another sign of rotator cuff tendinopathy is elicited by the *Neer test,* which suggests mechanical impingement with decrease of the subacromial space. The examiner forward flexes the arm, which causes impingement of the greater tuberosity of the humerus with the anterior and inferior edge of the acromion. The patient's shoulder should then be fully flexed to 180 degrees. A positive result occurs if there is pain produced at the end range of the arc.

The *Hawkins test,* also indicative of mechanical impingement, is performed by forcibly internally rotating the proximal humerus while the shoulder is forward flexed to 90 degrees and the elbow flexed to 90 degrees. Pain with this maneuver indicates a positive finding.

A complete rotator cuff tear is evaluated by the *drop arm test,* in which the arm is passively abducted at 90 degrees and the patient is asked to maintain the abduction. If the arm drops to the side, a large rotator cuff tear should be considered.[17]

The *shrug sign* is exhibited when a patient with acute macrotrauma to the rotator cuff is asked to abduct the arm at 90 degrees and appears to be giving a shrug with that side. This movement results from the scapula's attempting to abduct the arm without the assistance of the rotator cuff. Although this has historically been associated with rotator cuff disease, it is somewhat nonspecific and can be associated with other shoulder disease.[18] Patients with adhesive capsulitis (frozen shoulder) have limitation of active and passive range of motion.[19]

Bicipital Tendinopathy. The tendon of the long head of the biceps, given its insertion into the humerus in proximity to the rotator cuff, can be associated with the impingement syndrome. The patient with bicipital tendinopathy may report pain in the anterior shoulder that radiates down to the radius. Discomfort occurs when the individual rolls on the shoulder at night or attempts to reach a hip pocket or a back zipper. Focal tenderness can be obtained by palpation in the groove between the greater and lesser tuberosities of the humerus while testing for *Yergason's sign,* which is elicited by having the patient flex the elbow to 90 degrees with the arm against the body and resisting supination of the forearm. Pain in the area of the proximal tendon is considered to be a positive finding and indicative of bicipital tendinopathy.[17]

Another physical examination tool in the diagnosis of bicipital tendinopathy is the *Speed sign*. With the elbow extended and the forearm supinated, the patient is instructed to resist forward flexion of the adducted shoulder at 60 degrees. Pain in the area of the proximal biceps tendon (bicipital groove) is indicative of a positive finding. This may also be suggestive, however, of labral disease.[20]

Calcific Tendinopathy. Calcific tendinopathy is an acute or chronically painful condition associated with deposition of calcium crystals that occurs in or around the tendons of the rotator cuff. The cause is unknown but has been postulated to be related to tissue hypoxia and degeneration due to overuse.[21] Although it can affect any of the rotator cuff tendons, it seems to have a predilection for the supraspinatus. The symptoms are similar to those of an impingement syndrome, and the condition generally affects people older than 40 years. Calcium deposition

www.ketabpezeshki.com 66485457-66963820

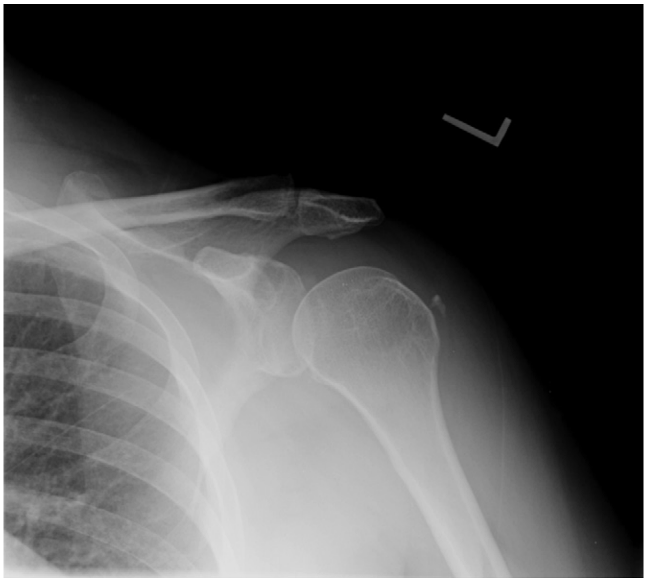

Figure 117-2. Plain radiograph of the shoulder showing calcium deposits of the rotator cuff in a patient with acute shoulder pain, consistent with calcific tendinopathy.

occurs over time and then undergoes spontaneous resorption. This resorptive phase is thought to be the painful aspect, but the severity of the symptoms is not related to the size of the deposit. Pain is believed to be in response to the local chemical pathologic disorder and direct mechanical irritation.[22]

On physical examination, there may be specific tenderness over the greater tuberosity as well as symptoms consistent with impingement. Radiographic evaluation may show evidence of calcification in or around the rotator cuff tendons (Fig. 117-2). The presence of calcium in the tendon does not necessarily affirm the origin of the pain because asymptomatic patients may have evidence of calcification on a routine radiograph.[22]

Elbow. Increasingly, athletes of all ages and skill levels are participating in sports involving overhead arm motions; consequently, elbow injuries are increasingly seen.[23] From an anatomic and functional perspective, the extensors and supinators of the wrist attach to the lateral elbow, and the flexors and pronators attach medially.

Lateral Epicondylitis. Lateral epicondylitis ("tennis elbow") is a painful elbow condition that occurs at the insertion of the common extensor tendon (extensor carpi radialis brevis) onto the lateral epicondyle of the humerus. Although it occurs in many tennis players, epidemiologic studies suggest that less than 5% of patients with such a syndrome actually play tennis. Activities such as driving in screws, use of a wrench, and repetitive work on an assembly line have also been implicated. Symptoms often begin as a dull ache on the outer (lateral) aspect of the elbow.[24,25] The discomfort can be exacerbated by activities that involve extension or supination of the wrist, such as grasping and twisting. *Cozen's test* is performed by having the patient keep the fist clenched while extending the wrist. The examiner grasps the forearm with the left hand while the right hand pulls the patient's hand toward flexion against the patient's resistance. A positive finding is pain at the lateral epicondyle, reproducing the patient's symptoms.[26]

Active extension of the long finger against resistance with the elbow in extension can also reproduce the pain over the lateral epicondyle at the insertion of the extensor carpi radialis brevis. In addition, patients will typically have tenderness to palpation just distal to the lateral epicondyle, over the origin of the extensor carpi radialis brevis.[26]

Radiographs can be helpful in cases with atypical or prolonged symptoms and to rule out other pathologic conditions. Approximately 20% of patients demonstrate tendon calcification or a reactive exostosis at the tip of the epicondyle.[24]

The differential diagnosis of lateral epicondylitis includes posterior interosseus nerve entrapment (motor aspect of radial nerve in forearm). Other associated lesions include plica, synovitis, chondromalacia, and adolescent osteochondral defect.[24]

Medial Epicondylitis. The pain of the less common medial epicondylitis ("pitcher's elbow" or "golfer's elbow") can result from microtrauma at the site of the insertion of the flexor carpi radialis on the medial epicondyle. It is important to differentiate medial epicondylitis from other causes of medial elbow pain, including medial ulnar collateral ligament injury. As a result of repetitive valgus stress placed on the joint, microtraumatic injury and valgus instability at the ligament can occur. With disruption of the medial ulnar collateral ligament, abnormal stress is placed on the articular surfaces, which may lead to degenerative changes and the formation of osteophytes.[27] In the case of medial epicondylitis, patients will generally have tenderness over the flexor-pronator origin slightly distal and anterior to the medial epicondyle. Pain can be reproduced by having the patient attempt wrist flexion and forearm pronation against resistance.[28]

Wrist

de Quervain's Tenosynovitis. The wrist and hand comprise several tendons that pass through thick, fibrous retinacular tunnels. These help prevent subluxation of the tendons and act as a pulley system. Overuse syndromes are thought to result from changes of the synovial lining between these tendons and retinaculum. de Quervain's tenosynovitis involves the synovial lining of the abductor pollicis longus and extensor pollicis brevis. Although the term *tenosynovitis* indicates an inflammation of the tendon sheath, it has been noted that there are many potential forms of tenosynovitis. Classic acute inflammatory changes that are characteristic of tenosynovitis may be related to systemic manifestations of disease (e.g., rheumatoid arthritis and gout); tenosynovitis related to de Quervain's syndrome is referred to by some practitioners as *stenosing tenosynovitis*. The pathologic process of de Quervain's tenosynovitis does not generally involve inflammation because the primary change is thickening of the extensor retinaculum covering the first dorsal compartment of the wrist. It has been suggested that de Quervain's disease is a result of intrinsic degenerative mechanisms rather than extrinsic inflammatory ones.[29]

The history may consist of chronic, repetitive trauma or unaccustomed repetitive efforts, such as firm grasping and movement of the hand in a radial direction. Direct trauma, such as a direct blow or fall, has occasionally been implicated.[30] The discomfort of de Quervain's tenosynovitis can be localized over the radial styloid process. Radiation of pain proximally to the forearm or distally down the thumb has been noted. The pain is generally constant but may be exacerbated by maneuvers that include grasping, abduction of the thumb, and ulnar deviation of the wrist. In most cases of de Quervain's tenosynovitis, the onset is gradual and not associated with a history of acute trauma.

On physical examination, slight swelling may be seen over the radial styloid. Crepitation may be palpable over the tendons with flexion and extension of the thumb. An increase in the tensile load (passive stretching or active contraction) in the abductor pollicis longus or extensor pollicis brevis increases pain. The *Finkelstein test,* which exacerbates the discomfort of de Quervain's tenosynovitis, is the most pathognomonic physical sign. The patient is instructed to hold the affected thumb in the palm by the fingers and then to ulnar deviate the wrist. Pain will occur near the radial styloid, which is also the point of tenderness. Pain with this maneuver is considered to be a positive finding. Radiographs are characteristically normal.

www.ketabpezeshki.com 66485457-66963820

The differential diagnosis includes scaphoid fracture and osteoarthritis of the carpometacarpal joint, which has pain caused by longitudinal traction and compression. Rarely, infections such as tuberculosis or disseminated gonococcal infections can be manifested as tenosynovitis.

Knee

Patellar Tendinopathy. Patellar tendinopathy or "jumper's knee" occurs in sports that have jumping as a part of the activity, although it can also occur as a result of other sporting activities.[31] Patients complain of pain at the inferior pole of the patella. The discomfort may abate with activity early in the tendinopathy but later progresses to the point of discomfort during exercise and at rest. With the knee flexed at 30 degrees, which relaxes the quadriceps, tenderness may be localized to the deep surface of the proximal attachment of the patellar tendon at the inferior pole of the patella. However, healthy active athletes sometimes have tenderness on examination as well.[31,32]

The differential diagnosis includes patellofemoral syndrome, which arises from imbalances in the forces controlling tracking during knee flexion and extension. The patient usually complains of anterior knee pain, described as "behind" or "around" the patella, which is classically worse on ascending or descending stairs or on rising from a seated position. On occasion, there is tenderness of the medial or lateral retinacula or facets.[33]

Imaging with ultrasonography and magnetic resonance imaging (MRI) may reflect collagen degeneration but is generally adjunctive to the distinctive history and physical examination findings. It is noted that some asymptomatic jumping athletes have imaging appearances similar to those of affected individuals and that prognosis and outcome are not predicted by such imaging.[31]

Ankle

Achilles Tendinopathy. Achilles tendinopathy is a common overuse syndrome that typically affects male athletes. The Achilles tendon, named for the mythological Achilles, whose heel was not immersed in the river Styx as his mother dipped him in the river for its protective powers, arises from the medial and lateral heads of the gastrocnemius muscle and the deep layers of the soleus muscle and inserts on the calcaneal tuberosity. A major function is plantar flexion of the foot. It is the strongest and largest tendon in the body and can withstand tensile loads more than 12 times the body's weight during running.[34]

The Achilles tendon is vulnerable to injury from either trauma or overuse. A tendinopathy can also develop as a result of systemic disease (e.g., ankylosing spondylitis, Reiter's syndrome, gout, and pseudogout). The use of fluoroquinolones has also been related to Achilles tendinopathy.[7]

The occurrence of Achilles tendinopathy is highest among individuals who participate in middle- and long-distance running, orienteering, track and field, tennis, badminton, volleyball, and soccer. Some studies have noted an almost 10% annual incidence of Achilles disorders in elite runners.[34] The most common Achilles disorders are tendinopathy (55-66%) and insertional problems, such as retrocalcaneal bursitis and insertional tendinopathy (20-25%).[34] Many cases of Achilles tendinopathy are thought to be multifactorial in origin. Body mechanics and environmental factors (e.g., uneven terrain) may apply valgus or varus stress to the tendon. Technique, equipment, and body mechanics can also contribute to the development of this tendinopathy. Anatomically, the vascular supply to the tendon creates a watershed area approximately 2 to 6 cm above the calcaneal insertion. This is thought to be responsible for clinical symptoms and the pathologic disruption commonly seen at this site.

The patient's history provides most of the information necessary to make the diagnosis of Achilles tendinopathy. Pain, a cardinal symptom of Achilles tendinopathy, may lead the patient to seek medical help. Some practitioners have noted that the patient's symptoms reflect the degree of the tendon abnormality. As with many tendinopathies, pain after strenuous activities is reported in the early phase, whereas pain in the later phase occurs during activity and even at rest. At this point, the patient is often unable to perform sporting activities.[34]

On physical examination, inspect the contour of the muscle-tendon unit and note areas of swelling and erythema. In acute Achilles tendinopathy, the tendon may be diffusely swollen and exhibit tenderness on palpation, usually greatest in the middle third. Typically, in the patient who has acute symptoms of tendinopathy, the area of swelling and tenderness does not move with dorsiflexion of the ankle joint. On palpation, local heat, crepitation, and palpable tendon nodules or defects may be noted. Examination for ankle instability and biomechanical faults should be considered.[34]

Achilles Tendon Rupture. Although rupture of the Achilles tendon most often occurs when it is preceded by tendon damage,[35] it is possible for untrained athletes to apply excessive force and to rupture the tendon in the absence of prior changes of tendinopathy. Partial and complete rupture may occur, most commonly in 30- to 40-year-old men. Complete rupture is more common in the middle-aged recreational athlete. Historically, the patient may note a "popping" sensation followed by acute weakness and inability to continue the exercise or sport. The patient may report that it felt as though someone kicked him or her in the back of the ankle or, if playing a racket sport, as if he or she were struck on the calf by a ball.

On physical examination, a defect in the tendon can sometimes be palpated. If enough time has elapsed to allow hematoma formation, bogginess may be noted over the injured area of the tendon. The ability to plantar flex the foot is not incompatible with a complete rupture of the Achilles tendon. There are multiple plantar flexors of the foot and toes. Muscles such as the tibialis posterior, flexor digitorum longus, flexor hallucis longus, peroneus brevis, and peroneus longus can remain functional and therefore disguise a complete rupture with the ability to plantar flex the foot. The *Simmonds (Thompson) test* can be performed to evaluate for complete rupture. With the patient prone and feet hanging over the edge of the bed, the examiner squeezes the calf muscles at their widest point and looks for passive plantar flexion. The absence of plantar flexion is considered a positive finding, indicative of a complete tear of the Achilles tendon. The presence of plantar flexion does not, however, negate the possibility of a partial tear of the Achilles tendon.

Diagnostic Strategies

The diagnosis of tendinopathy is generally made on clinical grounds. Although plain radiographs may be helpful in excluding bone abnormalities, ultrasonography has been recommended by some practitioners as the modality of choice for evaluation of pathologic tendon conditions.[36] Ultrasonography can be especially useful when other conditions (e.g., gouty arthritis) obscure the findings of concomitant tendinopathy. Although ultrasound imaging is employed in the emergency department (ED), the use of this imaging technique for soft tissue evaluation in this setting is relatively unstudied, and thus it is not frequently used.[37,38] In cases of acute or chronic tendinopathy, one or more of the following features can be seen: loss of the fibrillar echotexture, focal tendon thickening, diffuse thickening, focal hypoechoic areas, extended hypoechogenicity, irregular and ill-defined borders, microruptures, and peritendinous inflammatory edema.[39] Hypoechoic areas surrounding tendons provide evidence for surrounding soft tissue inflammation. In addition to tendinopathy, tendon tears, both partial and complete, can be delineated by ultrasonography.[39]

MRI has been used to visualize pathologic conditions of the tendon. It is able to provide high intrinsic tissue contrast, which

www.ketabpezeshki.com 66485457-66963820

permits the distinction between normal tendons and abnormal tendons, and the high spatial resolution that permits detailed anatomic structures to be identified. MRI has superb resolution of the soft tissue structures and can aid in a variety of tendon disorders. Cost, availability, the need to have the patient be still during examination, and the loss of the interactive and dynamic component compared with ultrasound examination are disadvantages to use of this modality.[40]

Differential Diagnosis

The differential diagnosis for tendinopathy includes tendon ruptures, bursitis, ligamentous injuries, septic and inflammatory arthritis, nerve entrapment syndromes, and bone abnormalities (such as fracture, foreign body, tumor, and osteomyelitis).

Management

General Tendinopathy

The management of tendinopathy focuses on identification of the cause of discomfort; elimination of sources of primary tendinopathy; institution of treatment modalities, such as analgesic medication, protection, relative rest, application of ice, compression, and elevation as necessary; modification of behavior to minimize or to eliminate sources of continuing irritation; and, importantly, referral for appropriate follow-up care.[5]

Cryotherapy (cold treatments, 20 minutes at a time every several hours, for the first 24 to 48 hours) may be beneficial. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also sometimes indicated to provide pain relief, although there is little evidence to support a beneficial effect with their use because tendinopathies tend to represent a degenerative rather than an inflammatory process.[41] Graduated range-of-motion exercises may be useful after the period of immobilization. Although corticosteroid injection is often used, its role for most tendinopathies is unclear.[42,43] The use of corticosteroid injection is controversial. Steroids should not be injected into a major tendon such as the Achilles tendon or the patellar tendon, which may be at risk for spontaneous rupture if it is already weakened.

Specific Tendinopathies

Impingement Syndrome and Rotator Cuff Tendinopathies. The treatment of rotator cuff tendinopathies and the impingement syndrome follows the treatment of tendinopathy in general. Emphasis is placed on physical rehabilitation and strengthening exercises. A significant proportion of patients will improve with conservative management. In those who do not, surgical intervention, such as acromioplasty or repair, may be indicated.[44,45]

Calcific Tendinopathy. The initial treatment of calcific tendinopathy is mainly conservative and consists of analgesia and brief sling immobilization because prolonged immobilization may result in adhesive capsulitis. The use of corticosteroids is controversial. Ultrasonography and extracorporeal shock wave therapy have been used with some success.[22] A small percentage of patients who do not respond to these interventions may need surgery. As well as arthroscopic treatment, localized disruption in the resorptive phase by needle lavage under fluoroscopic guidance or in the operating room has been noted to be an efficacious therapy.[21,22] Follow-up care is important because calcific tendinopathy has been described as the best known cause of reactive cuff failure.

Lateral and Medial Epicondylitis. In up to 95% of patients, epicondylitis will improve with conservative therapy.[24] Initial efforts include making the patient more comfortable with the standard principles of protection, relative rest, cryotherapy, compression, elevation, medication (NSAIDs), and modalities of physical therapy. The term *relative rest* implies the avoidance of abuse and not the absence of activity. Activities that aggravate the pain should be eliminated, and an attempt to protect the tendon through such strategies as a reduction in playing time or intensity should be considered. Control of force loads by bracing, improved performance technique, and use of appropriate equipment should also be considered.[24] Follow-up evaluation should be ensured.

de Quervain's Tenosynovitis. The initial treatment of de Quervain's tenosynovitis consists of immobilization with a thumb spica splint, anti-inflammatory medications, and prompt referral. Corticosteroid injection has been shown to be an effective treatment of de Quervain's disease, and failure to respond may be due to anatomic variation or poor technique.[29,46] Surgical decompression of the first dorsal compartment may be indicated if these treatments fail.[29]

Achilles Tendinopathy and Rupture. In addition to routine conservative treatment, patients with Achilles tendinopathy should be referred for orthopedic evaluation and correction of limb malalignment with the use of orthotics or heel lifts. Eccentric loading exercise and low-energy shock wave therapy are effective therapies for Achilles tendinopathy.[47-49]

The management of Achilles tendon rupture may be either operative or nonoperative, depending on the patient involved. Appropriate consultation with an orthopedist is essential. A conservative approach, including immobilization in a short or long leg cast in the equinus position, may be indicated.[50] Some authors note that complete ruptures in active athletes should be treated surgically in most cases.[51] Although other risks and benefits must be taken into consideration, some studies indicate that early surgery may be indicated because the risk for Achilles tendon re-rupture is less.[50,51]

Disposition

Most patients with tendinopathy are safely discharged home with proper discharge instructions, relative rest of the tendon, analgesia, and appropriate follow-up. The exception is elderly or disabled patients who are rendered unable to perform the activities of daily living by the tendinopathy. Although appropriate rest and analgesia provide symptomatic relief, underlying causes should be sought and modified.

BURSITIS

Perspective

Bursae are closed, round, flat sacs lined by synovium.[52] They occur at areas of friction between skin and underlying ligaments and bone. The bursa permits lubricated movement of soft tissues over areas of potential impingement (e.g., subacromial bursa) and friction (e.g., olecranon bursa and prepatellar bursa). Many bursae are nameless, and new bursae can form as a result of frequent irritation. The two most common identifiably inflamed bursae are the olecranon and the prepatellar. When these bursae are inflamed, they are generally recognizable over the extensor surface of the elbow or the knee, respectively.

Principles of Disease

Many cases of bursitis are idiopathic in nature, but common identifiable causes of inflammation include infection (most often due to *Staphylococcus aureus*), trauma (which may predispose to infection), rheumatologic disorders (e.g., gout, pseudogout, ankylosing spondylitis, and rheumatoid and psoriatic arthritis), and other systemic diseases.

www.ketabpezeshki.com 66485457-66963820

Clinical Features

Olecranon and Prepatellar Bursitis

Less than half of patients who present with olecranon or prepatellar bursitis show signs of an infectious origin.[53,54] Distinguishing septic from nonseptic bursitis is not always straightforward, either on clinical grounds or as a result of diagnostic testing. Patients with septic bursitis generally present earlier in the clinical course and have more pain, tenderness, erythema, and warmth compared with those who have an inflammatory process. The most important predisposing factor in septic bursitis is trauma, which precedes septic bursitis in up to 70% of cases.[52] Other predisposing factors for septic bursitis include chronic illness such as diabetes mellitus or alcohol abuse, chronic skin conditions such as atopic dermatitis, and previous noninfectious inflammation of the bursae such as rheumatoid arthritis or gout.[52] It may also be seen more commonly in people in occupations in which repetitive knee or elbow trauma is common.

The olecranon bursa, on the extensor surface of the elbow, is the only bursa of the elbow joint and is easily traumatized, resulting in inflammation, pain, and swelling. Infection can occur from local trauma (e.g., puncture wound and laceration) but may also be present in the absence of visible trauma. Hematogenous bacterial seeding is rare and is probably due to the limited vascular supply of the bursal tissue.[55]

On physical examination, localized swelling and fluctuance are usually present. Evidence of trauma may or may not be present. Tenderness and warmth are seen in most patients with septic bursitis. Erythema with overlying cellulitis is also common in septic bursitis, and approximately 40% of patients will also have a fever. Whereas tenderness, erythema, and warmth can also be seen in patients with purely inflammatory causes of bursitis, both the frequency and degree of these findings are less, and patients with septic bursitis will usually present earlier in the clinical course.[52,54]

Passive range of motion should not produce much pain, with the exception of full flexion, at which point there may be discomfort as the inflamed bursa is compressed. Evidence of significantly diminished range of motion, generalized joint swelling, or other signs and symptoms of joint involvement (e.g., joint pain, warmth, and joint effusion) should raise a concern for septic arthritis. Although the olecranon and prepatellar bursae generally do not communicate with the joint space, one must consider this possibility in the differential diagnosis, especially if trauma is involved and the integrity of the underlying joint is disrupted. Arthrocentesis to rule out septic arthritis should then be considered.

Diagnostic Strategies

When signs of acute inflammation are present, aspiration of the bursa is indicated to exclude the presence of infection or crystal-induced disease.[52,53] Although a discussion of the technique of bursal aspiration is beyond the scope of this chapter, it should be performed with sterile technique. An 18- to 20-gauge needle can be used to perform this procedure. A lateral approach has been recommended to lower the risk of iatrogenic sinus track formation, although the relation between the two is still somewhat unclear. A distal approach can also be used when the olecranon bursa is aspirated. In cases of septic bursitis, the aspirate usually appears purulent but can occasionally appear serosanguineous or straw colored. In the case of nonseptic bursitis, the aspirate may vary from bloody aspirate to straw colored. The aspirate of an inflamed bursa should be sent for evaluation of white blood cell (WBC) count with differential, microscopy for crystals (if crystalline disease is suspected), Gram's stain, appropriate cultures and sensitivities, and glucose level. A bursal fluid glucose–to–serum glucose ratio of less than 50% is almost exclusively seen in septic bursitis.

Organisms found on either Gram's stain or culture are diagnostic for septic bursitis. There are no definitive guidelines about use of the WBC count to distinguish between septic and nonseptic bursitis. A bursal fluid WBC count higher than $1000/\mu L^3$ is almost always seen, and one higher than $5000/\mu L^3$ suggests bursal fluid infection, even in the presence of a negative Gram's stain, but counts can be much lower in septic bursitis and above this level in nonseptic cases. Culture is the definitive test but will not be available during the initial evaluation. *S. aureus* is by far the most common organism in bursal infection, followed by other staphylococcal and streptococcal species, and this bacteriology has not changed in the last several decades.[56-58]

Because most cases of septic bursitis occur in the olecranon and prepatellar bursae, the diagnosis is made clinically in conjunction with aspiration. MRI can be used to aid in the diagnosis of inflammation or infection of deep bursae.[59,60] Ultrasonography has also been used as a modality for aspiration of deep bursae.[61]

Differential Diagnosis

Conditions that mimic bursitis include underlying fracture and osteomyelitis. Radiography and bone scan or MRI may be necessary to exclude these conditions. Other causes of the nontraumatic, nonseptic bursitis include rheumatoid arthritis, gout, pseudogout, scleroderma, ankylosing spondylitis, systemic lupus erythematosus, hypertrophic pulmonary osteoarthropathy, Whipple's disease, oxalosis, and idiopathic hypereosinophilic syndrome.

Management

Septic Bursitis

The optimal treatment of septic bursitis is uncertain because large-scale clinical prospective trials in this area are lacking. Debate remains about the use of outpatient (oral) versus inpatient (intravenous) administration of antibiotics, duration of therapy, use of needle aspiration and incision and drainage, and use of operative intervention.[54]

Patients who have bursal inflammation with suspicion (clinical or laboratory) of infection should be treated with appropriate antibiotics. Empirical therapy (including coverage for *S. aureus* and *Streptococcus* species) may be indicated until definitive culture results are available. The frequency of methicillin-resistant *S. aureus* (MRSA) in septic bursitis is unclear, although recent literature suggests that rates are low.[56-58] MRSA was found to be the most common cause of community-onset adult septic arthritis in one case series from an ED population, so empirical coverage for this organism in septic bursitis should be considered.[62] A trial of oral antibiotic therapy (up to 14 days) and treatment on an outpatient basis in the patient with uncomplicated bursitis and no underlying disease is reasonable. However, failure rates up to 67% have been reported for outpatient treatment of septic bursitis.[54] One of the largest observational studies on the successful outpatient treatment of septic bursitis showed an admission rate of only 1 of 118 patients, but all patients in this study received sequential intravenous antibiotics for approximately 4 days at an outpatient clinic followed by oral antibiotic therapy.[63] Treatment in an observation unit or inpatient setting with intravenous antibiotics therefore is a consideration for patients with significant symptoms, with overlying cellulitis, or unlikely to receive close follow-up.

Needle aspiration is a commonly used technique for the management of septic bursae. Successful treatment of septic bursitis can be achieved in patients receiving outpatient oral antibiotics

www.ketabpezeshki.com 66485457-66963820

after initial needle aspiration. Laupland and Davies[63] showed no difference between patients who received aspiration (51% of total patients) and those who did not, but the authors conceded that patients who had more severe disease were likely to be selected for drainage. Also, the diagnosis of septic bursitis was confirmed by culture in only 26% of these patients, potentially underestimating the importance of bursal drainage in patients with true septic bursitis.[52] Because needle aspiration is used for the diagnosis of septic bursitis, initial drainage at the same time seems warranted. Those with a purulent aspirate may require repeated aspiration at 1- to 3-day intervals if the effusion persists. In all cases, appropriate follow-up to assess response to therapy should be arranged. Warm soaks and wound care are also indicated. Surgical incision and drainage or bursectomy may also be necessary in severe, recurrent, or refractory cases.[54]

Nonseptic Bursitis

The optimal treatment of nonseptic bursitis has not been clarified. Most cases improve with conservative therapy, although complete recovery can take many months. Aspiration can be considered in the initial treatment of acute nonseptic bursitis. Further conservative therapy includes the administration of NSAIDs and application of a compression dressing with an elastic bandage to prevent recurrent swelling. Systemic causes of bursitis (e.g., crystalline disease) should be treated appropriately. Avoidance of local trauma is important for treatment and successful prevention of bursitis. Recurrent olecranon bursitis may be caused by underlying anatomic disorders such as bone spurs. Steroid injection into a nonseptic bursa has been used as a treatment modality, but multiple complications have been described, including skin atrophy over the bursa, chronic pain, development of septic bursitis, bleeding, postinjection flare as a result of release of microcrystals, and tendon rupture.

Disposition

Patients without underlying medical problems who present with uncomplicated septic bursitis can usually be discharged with appropriate oral antibiotics. Those with underlying diseases (e.g., immunocompromise, leukopenia, and diabetes) and those with systemic toxicity or severe bursal infection (e.g., purulent drainage) are candidates for intravenous antibiotics and inpatient therapy. Patients with a purulent aspirate may need repeated aspiration. Close follow-up is necessary to ensure response to therapy. Patients with presumed nonseptic bursitis require close follow-up as well.

Other Types of Bursitis

Subacromial Bursitis

The subacromial bursa lies between the supraspinatus tendon and the acromion. Subacromial bursitis is thought to be nearly synonymous with supraspinatus tendinopathy and may be involved in the stages of rotator cuff impingement. Pain and tenderness, localized to the lateral aspect of the shoulder, and signs of impingement may be noted on physical examination.[13] Although it is uncommon, septic subacromial bursitis can occur.[61]

Trochanteric Bursitis

The trochanteric bursa has both deep and superficial components. The deep bursa is located between the greater trochanter and the tensor fascia lata; the superficial bursa is located between the greater trochanter and the skin. In general, middle-aged or older women report acute or chronic pain over the bursal area as well as the lateral thigh. Lying on the hip and walking may exacerbate the pain. Trochanteric bursitis can occur as a complication of rheumatoid arthritis. On examination, the pain of superficial bursitis may be reproduced by hip adduction, and the pain of deep trochanteric bursitis may be reproduced with hip abduction. The hip joint has normal examination findings. Septic trochanteric bursitis has been described in the literature.[64]

Ischiogluteal Bursitis

The ischiogluteal bursa is located adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Inflammation, known as *weaver's bottom,* is described as pain over the center of the buttocks with radiation down the back of the leg. Sitting on a hard surface exacerbates the pain, and palpation over the ischial tuberosity causes discomfort.

Iliopsoas Bursitis

The iliopsoas bursa is the largest bursa around the hip. It lies between the iliopsoas tendon and the lesser trochanter. The pain of iliopsoas bursitis usually is manifested as anterior hip pain that can radiate down the medial thigh to the knee and is increased on hip extension.[65]

Anserine Bursitis

The anserine bursa lies deep to the three tendons (sartorius, gracilis, and semitendinosus) that form the pes anserinus ("foot of the goose") and superficial to the medial collateral ligament. The patient with anserine bursitis usually complains of medial knee pain approximately 2 or 3 cm distal to the joint line. There is usually tenderness to palpation in this area and occasionally swelling. Diabetes mellitus and possibly obesity and osteoarthritis of the knee are risk factors for development of this condition.[66]

KEY CONCEPTS

Tendinopathy

- Mechanical overload and repetitive microtrauma are key underlying mechanisms in the development of tendinopathy. Patients most often present with a history of progressively worsening localized pain after work- or sport-related activities that are repetitive in nature.
- Tendinopathy may also be associated with nonmechanical causes, including systemic manifestations of diseases and the use of fluoroquinolones.
- Most patients with tendinopathy can initially be treated with conservative measures, such as protection, relative rest, application of ice, medication, and elevation. Overuse syndromes can take at least 6 to 12 weeks to heal. Inform patients of this and provide appropriate referral for follow-up.
- Operative treatment may be indicated for selected cases of tendon injury that require primary repair (e.g., rupture of the Achilles tendon) or that have failed to respond to conservative treatment (e.g., impingement syndrome) and are amenable to surgical amelioration.

Bursitis

- Consider the possibility of an infectious cause in all cases of acute bursitis.
- The definitive diagnosis of bursitis is made by aspiration of the bursa and evaluation of the fluid.
- Septic bursitis is most commonly caused by *Staphylococcus aureus*.

www.ketabpezeshki.com 66485457-66963820

- Nonseptic bursitis may be traumatic, rheumatologic (e.g., gout and pseudogout), or idiopathic in nature. Other conditions, such as septic arthritis, osteomyelitis, and underlying fracture, are in the differential diagnosis of bursitis.
- The management of bursitis includes treatment with appropriate medication (antibiotics for septic bursitis, NSAIDs for nonseptic bursitis), rest, application of ice, compression, and elevation as well as prompt referral for appropriate follow-up. Hospitalization is considered for severe local infections, for patients who are immunosuppressed, and in the presence of high fever or systemic toxicity.

CHAPTER 118

Systemic Lupus Erythematosus and the Vasculitides

Robert T. Arntfield and Christopher M. Hicks

SYSTEMIC LUPUS ERYTHEMATOSUS

Perspective

Systemic lupus erythematosus (SLE) is a multisystem, autoimmune disorder that poses a challenge to the emergency physician with its protean and occasionally dangerous manifestations. Morbidity for SLE patients is typically mediated through organ inflammation and destruction or the consequences of therapeutic immunosuppression. Further complicating lupus is the frequent association with the antiphospholipid syndrome (APS) and its corresponding venous and arterial thromboses. The diagnostic criteria reflective of its complexity and immunologic basis were first described in 1971.[1] Today, the emergency department (ED) is a common venue for the evaluation and treatment of patients suffering from SLE.[2]

Epidemiology

SLE is present in 20 to 70 per 100,000 of the general population.[3] Although great variation in incidence exists worldwide, it is clear that two groups have consistently higher incidences: women, representing 90% of cases; and African Americans.[3] Dramatic rises in incidence of SLE have been described during the past several decades, but it is suspected that this may be due to the implementation of more sensitive diagnostic criteria.[4]

Principles of Disease

The exact etiology of SLE is not understood. It is likely to be related to multiple factors; genetics, environmental factors, race, hormones, medications, and immunology have all been implicated to varying degrees.

With women representing 90% of SLE cases,[5] a strong role for estrogen in disease development has been well supported in large cohort studies.[6-8] The disease also has a strong genetic link, with high rates of monozygotic twin concordance and tremendous genetic overlap at the human leukocyte antigen (HLA) alleles.[9]

Anatomy and Physiology

SLE may cause disease in nearly any organ system in the body through inappropriate immune response to self and is often described as the prototype of all systemic, autoimmune disorders. Like its cause, its exact pathophysiologic mechanism is not completely elucidated. When a cell cycle ends (apoptosis), intracellular contents, including DNA-rich nucleosomes, are released into the bloodstream. For patients with SLE, this cellular debris may be regarded as nonself (i.e., an antigen) by the immune system. After exposure to these self antigens, the familiar immunologic cascade of antigen-presenting cells, T cells, and ultimately B cells and their plasma cell progeny is exacted, and patients form autoantibodies against their own cellular contents.[10] These autoantibodies (which include anti–double-stranded DNA antibody, a commonly ordered rheumatologic assay in evaluation for SLE) may then mediate organ-specific disease and inflammation. This may occur through either direct attack and injury to parenchymal tissue or other mechanisms,[11] such as formation of immune complexes that are deposited in tissue.[12] On the basis of this immunologic understanding of the pathogenesis of SLE, the rationale for immunosuppression as both chronic and acute therapy for SLE can be appreciated.

The pathophysiologic mechanism of SLE may be different for each organ system. Indeed, the organ systems involved in any given patient's disease may be different and may relate to the underlying presence or absence of antigens that resemble tissue from that organ system.

Clinical Features

In general, there are four broad presentations for a patient with SLE: symptoms related to SLE that is not yet diagnosed (e.g., idiopathic pericarditis, new rash); progression or acute deterioration due to known SLE (e.g., progressive nephritis, lupus enteritis); complications of immunosuppression from treatment of SLE (e.g., opportunistic infection); and complaints or disease unrelated to SLE (e.g., trauma, pregnancy).

The Patient with Undiagnosed or Suspected SLE

Although some elements, such as the malar rash, that form the diagnosis of SLE are nearly pathognomonic for SLE, a confident initial diagnosis in the ED may otherwise be rare or difficult. The literature is replete with ED-based case reports of extreme initial presentations with conditions such as Guillain-Barré, cardiac tamponade, and fulminant renal failure that subsequently were confirmed as complications of unrecognized SLE[13-17]; however, in all cases the diagnosis of SLE was applied retrospectively. Because the workup for SLE is commonly conducted in a series of outpatient visits and relies on laboratory investigations that are uncommonly carried out in the ED, establishment of a new diagnosis of SLE in the ED is difficult. If a new diagnosis of SLE is suspected in an otherwise well patient, referral for an expedited workup is reasonable in most circumstances. The American College of Rheumatology classification criteria for SLE are presented in Table 118-1.[18,19]

www.ketabpezeshki.com 66485457-66963820

Table 118-1 American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus[18,19]

CONDITION*	DESCRIPTION
Malar rash	Butterfly-shaped, red rash on the face that spares the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging (atrophic scarring may occur in older lesions)
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Nonerosive arthritis	Two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	History or clinical evidence of either pericarditis or pleuritis; includes otherwise unexplained pericardial or pleural effusions
Renal disorder	Persistent proteinuria (>0.5 g/day) or cellular casts (red cell, hemoglobin, granular, tubular, or mixed)
Neurologic disorder	Otherwise unexplained seizures or psychosis
Hematologic disorder	Any of: hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
Immunologic disorder	Positive serology for any of: anti-DNA antibody, anti-Sm antibody, or antiphospholipid antibody (including anticardiolipin antibodies, lupus anticoagulant, or false-positive serology for syphilis)
Positive antinuclear antibody	Abnormal antinuclear antibody titer at any time in the absence of medications that may cause drug-induced lupus

*Patients exhibiting at least 4 of the 11 conditions listed here at any point in time meet the criteria for diagnosis of SLE.

Acute Presentations in the Patient with Known SLE

Emergency physicians are commonly faced with evaluating the acute complaints of patients with an established diagnosis of SLE.[2] The workup of SLE-related complications is based on use of a disease-specific differential diagnosis.

SLE Exacerbation

Even with good medication compliance, SLE patients are prone to exacerbations of their disease, typified by worsening physical symptoms from increased organ inflammation and destruction. These exacerbations may involve organs already affected by SLE or new conditions manifested in previously unaffected organ systems. As a systemic disease, worsening symptoms in one organ system should reasonably prompt evaluation for progressive disease activity in other organs. True to the broad scope of SLE, the most accepted scoring system to grade SLE exacerbations accounts for 20 different markers of disease activity across 9 organ systems.[20] Although such scoring systems have little role in the ED, it is important to identify when overall disease activity is increased as it typically signals the need to initiate or to escalate systemic therapy. In many cases, patients themselves are able to provide direction about the predictable course of their exacerbations and can be helpful in decision-making for therapy and disposition.

Specific Symptoms and Presentations

Fever. Improving survival for patients with SLE during the past several decades has been achieved with the use of improved immunosuppressive regimens. As a result, patients with SLE remain commonly affected by infections mediated by both typical and opportunistic organisms, suffering higher than average death rates from these infections.[21] In one case series, infection was the leading reason for SLE patients to be admitted to the intensive care unit, superseding both renal failure and cardiovascular disease.[22] Whereas absence of fever is insufficient in many cases to rule out infection, the presence of a fever is grounds for concern. Fever may also be due to increased overall disease activity.[23,24] Given the heightened risk for SLE patients with infection, determination that a fever is due strictly to disease exacerbation should be made cautiously.[21] The majority of infections in SLE are due to skin, lung, or urinary sources and are caused by typical organisms. However, largely because of the immunomodulating therapies that form the cornerstone of SLE management, opportunistic diseases are possible; *Pneumocystis (carinii) jiroveci* pneumonia, cryptococcal meningitis, *Listeria* infection, and herpes zoster have all been described.[25]

Neuropsychiatric Presentations. According to the American College of Rheumatology, there are 19 different clinical manifestations of neuropsychiatric SLE, some of which are included in the diagnostic criteria (see Table 118-1).[26] These 19 different presentations range vastly and include seizures, confusion, cranial neuropathies, demyelinating syndromes, myasthenia gravis, depression, psychosis, and anxiety. It may not be possible in the ED to determine whether such manifestations are due to neuropsychiatric SLE or to other, independent pathologic processes.

Headache. In general, headaches in a patient with SLE may be evaluated in a fashion similar to that for headaches in the general population. In one prospective cohort study, for instance, it was found that primary headache disorders, such as migraine and tension headaches, occur with the same frequency in SLE patients as in the general population.[27] This was further supported by an extensive meta-analysis examining the implications of headache in SLE patients.[28] In this study, the authors found no relationship between headache and SLE disease activity. Thus, despite recommendations to consider headache as suggestive of neuropsychiatric SLE or so-called lupus cerebritis,[26] isolated headaches in the context of lupus may be treated in a fashion typical of other primary headache disorders. When a more malignant cause of headache is suspected, as suggested by meningismus, fever, or focal neurologic findings, an aggressive workup is warranted. When concern exists for an infectious cause of headache, consideration for opportunistic infections, such as cryptococcal meningitis, should be made in an immunosuppressed SLE patient.[29] Further, because of common comorbid APS, consider sinus thrombosis in the SLE patient with new-onset focal central nervous system findings and headache.[30]

Seizure. Because of incompletely understood mechanisms, seizures may occur as result of SLE disease activity. In one large series, seizures were observed in 11% of SLE patients, and in the majority of cases, either stroke or comorbid APS was present.[31] Because of the high incidence of seizures, nonconvulsive status epilepticus is a consideration in SLE patients with an acute onset of altered mental status. The workup and management of seizures do not differ between patients with SLE and the general population.

Focal Neurologic Findings. On occasion, the patient with SLE may present with focal motor weakness. In those with SLE who also have APS, there is a significantly increased risk of stroke related to spontaneous arterial thrombosis.[32] Demyelinating disease, such Guillain-Barré and cranial neuropathies, have also been occasionally attributed to SLE from unclear mechanisms.

www.ketabpezeshki.com 66485457-66963820

Table 118-2 Chest Pain and SLE in the Emergency Department: Common Causes, Workup, and Treatment

CONDITION	DIAGNOSTIC TEST IN THE ED	TREATMENT	COMMENT
Pleuritis	Clinical, chest radiography (for commonly associated pleural effusion)	NSAIDs ± steroids	Diagnosis of exclusion
Pulmonary embolism	D-dimer, computed tomography pulmonary angiography	Anticoagulation	Higher incidence in all SLE patients, especially those with APS
Pneumonia	Chest radiography	Antibiotics	Consider opportunistic disease
Pericarditis	Electrocardiography	NSAIDs ± steroids	Echocardiography to rule out effusion; electrocardiographic findings in less than 50%
Coronary artery disease	Electrocardiography, troponin, CK-MB	Aspirin, heparin, percutaneous coronary intervention	++ Increased prevalence in SLE

APS, antiphospholipid syndrome; *CK-MB,* creatine kinase MB fraction; *ED,* emergency department; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

Psychiatric Symptoms. Mood disorders, psychosis, and anxiety are considered potential manifestations of neuropsychiatric SLE.[26] Distinguishing SLE-related from functional causes of psychiatric presentations poses a challenge and may not be possible in the ED. Although psychiatric presentations of SLE in the ED have not been directly studied, in the absence of concern for an organic cause of altered mental status, patients with SLE are approached in the same manner as patients without SLE. Corroboration with the patient's rheumatologist may provide insight to history of similar events or guidance for treatment.

Cardiorespiratory Presentations and Diseases. Chest pain, in the form of either pleuritis or pericarditis, is among the diagnostic criteria for SLE (see Table 118-1). In addition to pericarditis and pleuritis, coronary artery disease (CAD), pulmonary embolism, and musculoskeletal causes are also common. Other forms of cardiac disease that occur without chest pain, such as verrucous (Libman-Sacks) endocarditis and various arrhythmias, may also be present.[15]

Coronary Artery Disease. There is a dramatically increased risk of CAD in the context of SLE. This was demonstrated in a compelling retrospective cohort study of 500 women with lupus compared with age-matched controls from the original Framingham data. In this study, a 52-fold increased risk of myocardial infarction was determined in women between the ages of 35 and 44 years.[33] These findings of increased risk of CAD have been supported by a number of other prospective trials. In one series, patients with SLE were found to be five times as likely to have CAD (based on coronary artery calcium scoring) as patients without SLE.[34] In another series that profiled an even younger subset, it was found that among otherwise low- to moderate-risk women aged 22 to 45 years with complaints of chest pain, dyspnea, or decreased exercise capacity, there was an alarming 82% prevalence of CAD as determined by nuclear imaging. There was a similarly concerning prevalence of 43% of CAD in the asymptomatic "control" group who also had SLE.[35] Further, traditional cardiac risk factors are found less often in patients with SLE who suffer consequences of CAD, suggesting that CAD in patients with SLE cannot be explained by the higher incidence of hypertension or hypercholesterolemia that these patients often exhibit.[36] Thus, whereas there are many considerations for the cause of chest pain in patients with SLE (Table 118-2), CAD must be considered highly, and in fact more highly in patients who would otherwise be deemed to be low risk (young, reproductive age women). It is therefore appropriate to have a low threshold to initiate a workup with electrocardiography, cardiac biomarkers, and stress testing to rule out acute coronary syndromes in patients with chest pain and SLE.

In addition to being at risk for development of CAD, patients with SLE who are treated with percutaneous coronary intervention appear to fare poorly. In one retrospective analysis of 28 patients with SLE receiving percutaneous coronary intervention, reintervention, death, and recurrent myocardial infarction were significantly more likely compared with a similar cohort without SLE.[37]

Pericardial Disease. Pericardial effusion and pericarditis occur commonly in patients with SLE. It is estimated that symptomatic pericarditis occurs in 25% of patients with SLE during the course of their lives and that pericardial effusion occurs even more often, frequently in a silent fashion, in up to 50%.[38] In clinically evident SLE-related pericarditis, dyspnea or pleuritic chest pain is common. Typical electrocardiographic findings (Fig. 118-1) have been shown to be present in less than half of cases, however.[39] Given the increased risk of CAD in patients with SLE, ST elevation of any kind found on an electrocardiogram warrants very careful consideration. When diagnostic uncertainty exists, echocardiography, cardiac enzymes, or cardiac catheterization may be complementary. Treatment of pericarditis includes nonsteroidal anti-inflammatory drugs (NSAIDs) and glucocorticoids, as discussed later.

Pericardial tamponade, because of its dramatic nature, continues to receive attention as an initial presentation of SLE[40]; however, large case series have shown that this life-threatening presentation occurs in less than 1% of patients with lupus.[41] In large effusions without tamponade, medical management with high-dose glucocorticoids (1-2 mg/kg of methylprednisone) has shown favorable outcomes in averting the need for pericardiocentesis.[39]

Pulmonary Embolism. Pulmonary embolism and deep venous thrombosis occur with increased incidence in patients with SLE. This is especially true for patients with SLE who also carry antiphospholipid (aPL) antibodies. These patients have an estimated 20- to 30-fold increased risk for thrombosis compared with the general population. Patients with SLE who do not have aPL antibodies still have a sixfold greater likelihood for development of pulmonary embolism and deep venous thrombosis compared with patients without SLE.[42,43] Thus, all patients with SLE, regardless of their aPL antibody status, which is often unknown on presentation, should be considered at increased risk for venous thromboembolism.

Pleuritis. Pleuritis, due to autoantibodies acting against the pleura itself, is the most common respiratory condition occurring in SLE.[44] Characterized by pleuritic chest pain with or without a pleural effusion or pleural rub, it has symptoms that overlap with those of other more serious conditions (see Table 118-2). If a pleural effusion is present, analysis of pleural fluid for antinuclear antibodies may be the most accurate method to confirm diagnosis but may be impractical in the ED.[45] A diagnosis of pleuritis should be arrived at only after other causes of pleuritic chest pain in these thrombophilic, immunosuppressed patients have been ruled out.

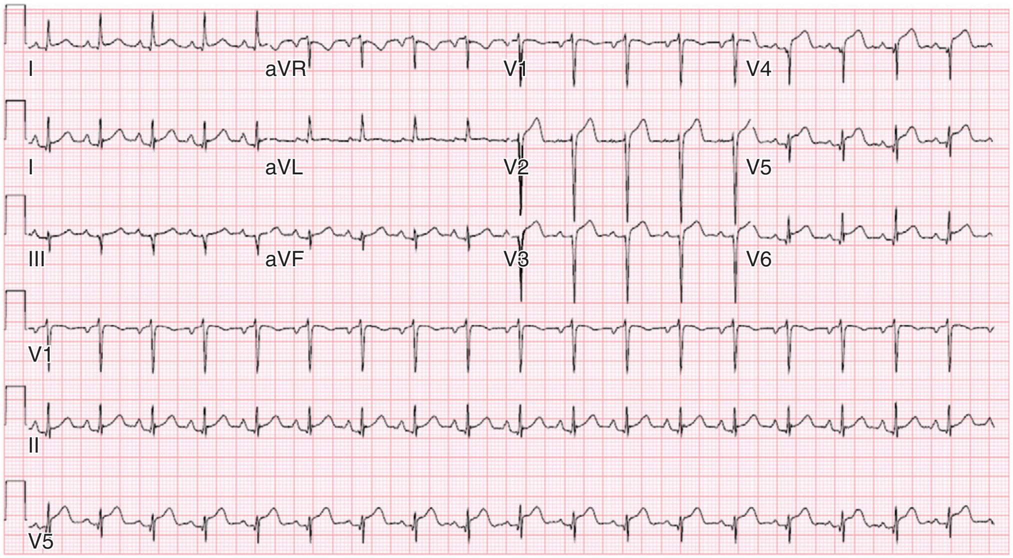

Figure 118-1. Electrocardiogram of a 38-year-old woman with SLE who presented to the ED with seizures and had chest pain while in the ED. Note diffuse ST elevation (with absence of any reciprocal changes) and PR depression (particularly evident in lead II). Q waves anteriorly are related to prior myocardial infarct.

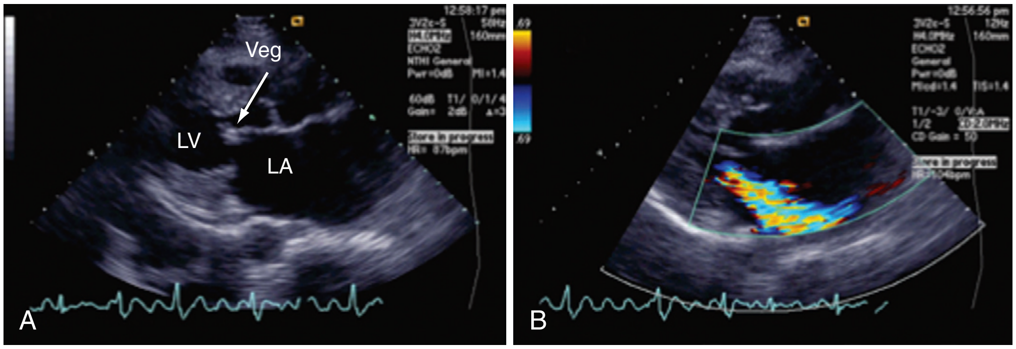

Figure 118-2. Noninfectious endocarditis, known as a Libman-Sacks lesion, in a 56-year-old woman with SLE, a heart murmur, and dyspnea on exertion. **A,** A parasternal long-axis view of the heart; a vegetation is identified (*arrow*) on the mitral valve. **B,** When color flow is superimposed on the valve, moderate to severe mitral regurgitation can be seen as a color jet entering the left atrium during systole. *LA,* left atrium; *LV,* left ventricle. (Courtesy Martin Goldman, MD, Mount Sinai School of Medicine.)

Musculoskeletal Chest Pain. Musculoskeletal chest pain, related to underlying pectoral, intercostal muscle, or costochondral joint inflammation, may also occur in SLE. Similar to pleuritis, the threat of a more malicious underlying cause of pain should prompt the clinician first to seek other causes before arriving at this more benign cause. Treatment with NSAIDs or acetaminophen is generally appropriate.

Pneumonia. Pneumonia is the third most common infection in patients with lupus, after skin and urinary tract infections.[44] Choice of antimicrobial coverage is determined by the severity of the infection and the degree of immunosuppression. For patients receiving long-term glucocorticoids or cyclophosphamide, coverage for organisms such as *Pseudomonas* and *Legionella* generally requires the use of a carbapenem or a fourth-generation cephalosporin in addition to either a respiratory fluoroquinolone or macrolide. There is no evidence to support the routine coverage for *P. jiroveci* in these patients.

Undifferentiated Dyspnea. Mitral valve insufficiency due to noninfectious vegetations, known as Libman-Sacks lesions, may cause a patient to experience dyspnea on exertion or, in rare severe cases, pulmonary edema (Fig. 118-2). Anemia, present in up to 50% of patients with SLE, may lead to a chief complaint of dyspnea. Both anemia of chronic disease and hemolytic anemia are common; hemolytic anemia is more typical in those also carrying aPL antibodies.[46] In cases of severe anemia recognized in the ED, a Coombs test can be diagnostic for immunologic hemolytic anemia. Other less common but noteworthy causes of shortness of breath in a patient with SLE include interstitial lung disease, lupus pneumonitis, diaphragmatic disease (so-called shrinking lung syndrome), and pulmonary hypertension.[47]

Musculoskeletal Presentations. Arthritis commonly afflicts those with SLE, and increasing severity of joint pain may be a marker of increasing disease activity or an SLE flare.[20] Arthritis or arthralgias are typically symmetrical and nonerosive (unlike rheumatoid arthritis) and may involve multiple joints. Arthritis is most commonly present in the hands, wrists, and knees but may be manifested in any joint. Aside from mild tenderness, the joints are often normal to physical examination and rarely experience deformity.[48] Uncommonly, septic arthritis may complicate SLE. In one large retrospective analysis of SLE-related hospitalizations, only 0.3% of admissions were for septic arthritis.[49] Possibly because of immunosuppressant use, including corticosteroids, *Salmonella* is an unusually frequent culprit organism that was isolated in 59% of cases in one study and most commonly found in the hip.[49] An

isolated swollen joint is not typical of SLE and prompts consideration for infectious arthritis. If septic arthritis is suspected, diagnostic arthrocentesis is recommended. Empirical treatment with 1 g of vancomycin and 1 g of ceftriaxone will cover likely organisms, including *Salmonella*. Myalgias are common in SLE and may be an early marker of increasing disease activity for some patients. Generalized muscle pain is typical, but muscle weakness is uncharacteristic.[50] If muscle weakness is present, an underlying myositis or myopathy secondary to steroid use is considered.

Gastrointestinal Presentations. The most common gastrointestinal manifestation of SLE is oral ulceration, which occurs in nearly a third of patients with SLE. Treatment includes local symptom management (chlorhexidine mouthwashes, viscous lidocaine) combined with systemic therapy (hydroxychloroquine) in more severe or refractory cases.[51] Abdominal pain commonly complicates SLE.[52] The causes of abdominal pain, with the exception of lupus enteritis, are largely similar to those in patients without SLE, such as pancreatitis, gastroenteritis, and peptic ulcer disease.[53] Lupus enteritis (also known as mesenteric vasculitis) typically results in diffuse abdominal pain and is the most common cause of acute abdominal pain in SLE.[53,54] The abdominal pain itself may also be associated with nausea, vomiting, and nonbloody diarrhea.[55] Laboratory investigations, such as white blood cell count, hemoglobin level, platelet count, and erythrocyte sedimentation rate (ESR), are not helpful as they do not differ significantly between those with enteritis and those with abdominal pain due to other causes.[53] Although no "gold standard" for the diagnosis of lupus enteritis has been established, computed tomography (CT) is the most useful test to assess for this condition. Several CT scan findings are supportive, including bowel wall thickening (Fig. 118-3), engorgement of mesenteric vessels, and increased attenuation of mesenteric fat.[56]

When lupus enteritis is suspected, early pulse steroids, at a dose of 1 to 2 mg/kg of methylprednisolone per day, should be administered. Surgical consultation should be obtained in severe cases or when bowel necrosis has occurred. With aggressive medical therapy, which may also include cyclophosphamide, the need for surgical management is uncommon.[53] Other, less common gastrointestinal illnesses to which SLE patients are predisposed include protein-losing enteropathy and intestinal pseudo-obstruction.[57] Last, in assessing abdomen pain in patients with SLE, clinicians should be mindful of the effects of chronic steroid use and increased risk for both hollow viscus perforation and peptic ulcers, which may occur in the absence of traditional symptoms.

Dermatologic Presentations. The most characteristic cutaneous manifestation of SLE is the malar rash. The rash has a "butterfly" distribution of raised erythema over the bridge of the nose and malar eminences while sparing nose and nasal-labial folds (Fig. 118-4). The other most common skin lesion found in SLE is the discoid rash. Discoid lesions are circular and raised, scaly lesions that may be commonly found on the face, scalp, and ears, often in association with pigment change, alopecia, and severe scarring (Fig. 118-5). Cutaneous lupus may exist in isolation without systemic involvement. Mild cases of worsening cutaneous lupus are treated topically with 1% hydrocortisone cream. Moderate to severe cases are treated with topical calcineurin inhibitors or even systemic therapy (e.g., hydroxychloroquine) in consultation with the patient's internist or rheumatologist.[58] In nearly all cases of SLE, avoidance of sun exposure is advisable and will help minimize cutaneous disease.

Renal Disease. Renal disease develops in approximately a third of SLE patients.[44] Given a high prevalence and morbidity of renal disease as well as its tendency to carry few if any symptoms, screening urinalysis and assessment of renal function are prudent in nearly all but the most straightforward presentations of SLE to the ED. Lupus nephritis may cause a nephrotic-type disease, primarily characterized by proteinuria (>2 g/day) or a more nephritic

www.ketabpezeshki.com 66485457-66963820

picture with hematuria and increased creatinine concentration.[59] If worsening renal dysfunction is discovered, admission should be considered for hydration and escalation of therapy that may include both pulse steroids and cyclophosphamide.

Complications due to Medications

The remarkable improvements in life expectancy and disease control in SLE carry a cost. Chronic steroid use is associated with a well-known host of consequences, such as increased risk of CAD, osteoporosis, avascular necrosis, psychosis, hyperglycemia, and weight gain, among many others. More potent chemotherapeutic medications, such as cyclophosphamide, methotrexate, and azathioprine, may profoundly influence the patient's immune response and cause increased vulnerability to conventional and opportunistic infections. Chronic NSAID use for the musculoskeletal consequences of SLE may contribute to peptic ulcer disease, especially if they are coadministered with glucocorticoids. Therapy with antimalarials, such as hydroxychloroquine, is common and generally well tolerated; however, retinopathy and both QT interval prolongation and refractory ventricular arrhythmias have been associated with prolonged use.[60]

Diagnostic Strategies

Diagnostic tests will depend on the patient's presentation and whether a diagnosis of SLE is already established or being suspected for the first time.

Laboratory

In all but the most trivial presentations, order a serum creatinine concentration, urinalysis, and complete blood count because renal dysfunction, proteinuria, anemia, or thrombocytopenia may silently complicate SLE and be an important marker of increased disease activity. Leukocytosis, already a nonspecific finding, may be even less contributory in SLE patients taking glucocorticoids. When a new diagnosis of SLE is being entertained, other more specific immunologic assays, such as antinuclear antibody, anti-DNA, anti-Sm antibody, and aPL antibody, can be ordered in the ED with the intent of outpatient follow-up for evaluation of results. Of note, antinuclear antibody is present in nearly all SLE patients but is also present in 50% of people who do not have SLE. Thus, the absence of antinuclear antibody virtually excludes the diagnosis.[61] Unlike in other inflammatory disorders, C-reactive protein does not typically rise in response to increased disease activity in SLE. It does, however, rise in the setting of infection and thus may be a useful laboratory marker to distinguish between a flare and infection. The ESR has less of a role as it has been shown to be elevated in SLE patients experiencing either a flare or an infection.[62] Coagulation profile may show an elevated partial thromboplastin time (PTT) with a normal international normalized ratio (INR) in patients with SLE. In these cases, suspicion for comorbid APS should be raised (see later section on special considerations).

Radiology

Radiography. In SLE, a chest radiograph may point to diagnoses such as pleuritis (pleural effusion); pericardial disease (enlarged cardiac silhouette); pneumonia, including atypical and opportunistic infections (airspace disease); and pulmonary embolism (normal).

Computed Tomography. CT scanning may be of particular value in identifying lupus enteritis in the patient with abdominal pain, and CT pulmonary angiography has become the preferred imaging modality for pulmonary embolism. In both cases, attention to the presence or absence of lupus nephritis must be made to guide the appropriate and safe use of intravenous contrast material.

Special Tests

Bedside echocardiography may be carried out to evaluate the presence of pericardial fluid when pericarditis is suspected on the basis of clinical or electrocardiographic findings. A number of studies have documented the safety and accuracy of emergency physicians' identifying pericardial effusions with point-of-care ultrasound examination.[63]

Nuclear imaging may be helpful to assess for pulmonary embolism in patients with chronic kidney disease due to lupus nephritis.

Differential Diagnosis

In keeping with its highly varied presentations and permutations of disease activity, a number of other diseases may be confused with early SLE before its proper diagnosis. These include undifferentiated connective tissue disease, primary Sjögren's syndrome, primary APS, fibromyalgia with positive antinuclear antibody, idiopathic thrombocytopenic purpura, drug-induced lupus, and early rheumatoid arthritis.[64] For those with an established diagnosis of SLE, chief complaint–driven considerations for acute presentations are listed in Table 118-3.

Management

Nearly all noninfectious consequences of SLE are managed with introduction or escalation of immunomodulatory therapy. In the majority of disease states, a pulse dose of methylprednisolone at 1 to 2 mg/kg is appropriate. See Table 118-4 for additional therapeutic options for escalating disease severity.

For SLE patients presenting with infection who are receiving chronic steroid therapy, consider stress dose glucocorticoids, hydrocortisone 50 to 100 mg intravenously every 8 hours, in addition to appropriate antimicrobial coverage.

Table 118-3 Common or Specific Differential Considerations for Patients with SLE Based on Common Presentations, Comorbidities, or Complications

CHIEF COMPLAINT	CONDITION
Pleuritic chest pain	Pericarditis, pleuritis, pulmonary embolism, pneumonia, musculoskeletal chest wall pain
Delirium	Neuropsychiatric lupus, steroid psychosis
Leg swelling	Deep venous thrombosis, renal failure, right-sided heart failure (pulmonary embolism, pulmonary hypertension), protein-losing enteropathy
Shortness of breath	Pneumonia, anemia, pericarditis or pericardial effusion, pleuritis or pleural effusion, interstitial lung disease, shrinking lung syndrome
Pruritic or painful rash	Discoid SLE, drug reaction, sun exposure
Abdominal pain	Lupus enteritis, peptic ulcer disease, pancreatitis, pseudo-obstruction
Fever	Infection, increased disease activity
Arthritis	Arthralgias (lupus flare), osteoarthritis, septic arthritis, unrelated (gout, fibromyalgia)

www.ketabpezeshki.com 66485457-66963820

Table 118-4 Medications and Typical Dosing Range for Acute Exacerbations of SLE

MEDICATION	MEDICATION CLASS	TYPICAL STARTING DOSE AND ROUTE
Methylprednisolone	Glucocorticoid	1-2 mg/kg IV, once daily
Prednisone	Glucocorticoid	1-2 mg/kg, PO, once daily
Hydroxychloroquine	Antimalarial	200-400 mg PO, once daily
Cyclophosphamide	Alkylating agent	500-750 mg/m^2 IV, once
Azathioprine	Antimetabolite (purine analogue)	25-50 mg/day (IV or PO)

NSAIDs

Much of the pain and morbidity associated with SLE is related to inflammation that is amenable to treatment with NSAIDs. Ibuprofen 400 to 600 mg orally four times a day or naproxen 500 mg orally twice daily is useful for conditions such as pericarditis, pleuritis, arthralgias, myalgias, and fever. Use of NSAIDs in patients with chronic kidney disease due to lupus nephritis or a history of peptic ulcer disease is discouraged. In such patients, acetaminophen is used for mild to moderate pain, and narcotics are recommended for severe pain.

Dermatologic Treatment

In cases of isolated cutaneous findings, topical treatment with corticosteroids is preferable to systemic therapy. Topical therapy may be initiated with 1% hydrocortisone cream to the affected area. In cases in which higher potency topical steroids are necessary, a preparation of 0.05% betamethasone applied once daily to the affected area for 2 weeks is appropriate.[65]

Special Considerations

Antiphospholipid Syndrome

Present in nearly 40% of SLE patients,[66] the antiphospholipid syndrome (APS) is considered when patients both have a clinical history of thrombosis and are carriers of any one of a particular set of aPL antibodies directed against three specific serum proteins.[67] These antibodies include the anticardiolipin antibody, the misleadingly named lupus anticoagulant, and the anti–β_2-glycoprotein I antibody. The most thrombogenic of the antibodies is the lupus anticoagulant, with an odds ratio as high as 16 for the development of venous thromboembolism and 10 for arterial thrombosis (stroke).[32] In addition to being a strong risk factor for both venous and arterial thrombosis, the presence of APS in SLE has been shown to be an independent predictor of more severe disease[68] and to be associated with increased intensive care unit mortality.[44] Whether it is present in the context of SLE or independently, APS is an important cause of morbidity and mortality due to thrombosis.[32,69]

Clinical Features. APS may present with any number of clinical features (Box 118-1), typically related to thrombosis or thromboembolism. A small subset of those with APS may present with multiple thrombotic sites and organ failures simultaneously. This condition is known as catastrophic APS.

Box 118-1 Common Clinical Features of the Antiphospholipid Syndrome

Venous thrombosis
Arterial thrombosis (including stroke and transient ischemic attack)
Recurrent miscarriage
Livedo reticularis
Thrombocytopenia

Diagnostic Strategies. Assays to detect and to measure the presence of aPL antibodies are not generally available in a timely fashion and are impractical for use in the ED setting. However, there are two laboratory findings supportive of APS that may be useful or accidentally discovered during an ED workup:

1. A spuriously elevated PTT in the setting of a normal PT/INR may reflect APS. This in vitro finding, which contradicts the actual in vivo hypercoagulable state of the APS patient, is due to interference of the coagulation study by aPL antibodies. Confirmation of the presence of the interfering antibody is done by carrying out a mixing study. A mixing study requires repeating the PTT with a mixture of the patient's blood and a 50% contribution from normal, control serum. In the presence of an inhibiting antibody, the PTT will remain elevated. If, however, the PTT was elevated for other reasons (most commonly heparin), the addition of normal clotting factors from the control serum will restore the PTT to normal.
2. The VDRL assay to test for syphilis contains cardiolipin and thus will commonly be falsely positive in patients with anticardiolipin antibodies or APS.

Treatment. For acute thrombotic events, anticoagulation with either unfractionated or low-molecular-weight heparin is generally indicated. After an initial thrombotic event, anticoagulation with vitamin K antagonists to maintain an INR between 2.0 and 3.0 is recommended. For patients with arterial thrombotic events (e.g., stroke) or recurrent venous thromboembolic events, anticoagulation is recommended indefinitely.[70] For patients suffering catastrophic APS, in addition to anticoagulation and glucocorticoids, intravenous immune globulin (IVIG), cyclophosphamide, and plasma exchange may all be indicated. Despite aggressive treatment, mortality for catastrophic APS approaches 50%.[71]

Drug-Induced Lupus

Drug-induced lupus is an SLE-like self-resolving illness characterized by arthralgias, myalgias, rash, and serositis; it may be brought on by as many as 80 different medications.[72] Notably, the malar rash and major organ involvement are rare in this condition.[73] In drug-induced lupus, antibodies against the body's own histone proteins are common and purported to be a major mechanism of disease.[74] Although the list of potentially implicated medications is long, those agents with most evidence for causing drug-induced lupus are summarized in Box 118-2. The diagnosis is typically clinical and confirmed by resolution of symptoms with the withdrawal of the offending medication. In addition to cessation of the culprit drug, NSAIDs or steroids for symptom control are indicated.

Disposition

Dispositions for the patient with SLE will vary significantly by clinical presentations. For patients with non–life-threatening presentations, such as increased musculoskeletal symptom burden, simple headache, or cutaneous reactions, discharge with appropriate follow-up is usually appropriate. However, patients with poor insight into their disease, significant comorbidities, or weak social or home supports may require admission.

With disorders characteristic of SLE flares (e.g., progressive lupus nephritis, lupus enteritis), new thrombotic events, and

www.ketabpezeshki.com 66485457-66963820

infectious complications due to immunosuppression, the patient may need admission for initiation of systemic therapy (e.g., glucocorticoids, anticoagulation, antibiotics) and evaluation of response or deterioration. Admission to the intensive care unit is considered for those who, despite initial resuscitation, suffer progressive circulatory or respiratory derangement. Because of the high incidence of CAD in patients with SLE, patients with undifferentiated chest pain who have acute coronary syndrome ruled out in the ED should receive an expedited evaluation with provocative testing (e.g., exercise stress test) in a chest pain unit or on an outpatient basis. If an outpatient workup is pursued, prescribe daily aspirin therapy. The complexity of SLE often challenges physicians not specialized in its many nuances and intricate pathophysiologic changes. Reasons for rheumatologic referral of patients with SLE are presented in Box 118-3.[75]

VASCULITIDES

Perspective

The vasculitides are a heterogeneous group of disorders characterized by inflammatory damage of blood vessels. Arteries and veins of all sizes and their tributaries can be affected to varying degrees. Presentations can range from benign and self-limited to serious and life-threatening. Diagnosis can be challenging as early vasculitis syndromes are nonspecific and can mimic other infectious, inflammatory, or neoplastic conditions. Approximately 1 in 2000 adults are affected by some form of vasculitis, with a higher incidence in adults 65 to 74 years of age.[76] In the United States, the most common vasculitis syndromes are giant cell arteritis, Wegener's granulomatosis, and microscopic polyangiitis.[77]

Box 118-2 Drugs Definitively Implicated in Causing Drug-Induced Lupus[72]

Chlorpromazine	

Box 118-3 Reasons for Rheumatologic Referral for Patients with SLE

- To confirm a diagnosis
- To assess disease activity and severity
- To provide general disease management
- To manage uncontrolled disease
- To manage organ involvement or life-threatening disease
- To manage or prevent treatment toxicities
- Special circumstances: antiphospholipid syndrome, pregnancy, surgery

Modified from Guidelines for referral and management of systemic lupus erythematosus in adults. American College of Rheumatology Ad Hoc Committee on Systemic Lupus Erythematosus Guidelines. Arthritis Rheum 42:1785-1796, 1999.

Principles of Disease

The cause of most vasculitis syndromes is unknown. Most cases are believed to result from immune complex deposition in blood vessel walls, prompting a complement-mediated inflammatory reaction. This results in vessel wall damage and necrosis, leading to stenosis, occlusion, and subsequent end-organ ischemia. The clinical manifestations are determined predominantly by the size and distribution of blood vessels involved along with the histologic subtype of inflammation.

The most recognized system for classification of the primary vasculitis is by the size of blood vessel involved (Table 118-5). Large-vessel vasculitis involves the aorta and its immediate branches and in some cases the corresponding vessels in the venous system. Medium-vessel disease involves the macrovasculature downstream from the main aortic branches. Small-vessel vasculitis involves capillaries, venules, arterioles, and glomeruli.

Clinical Features

Virtually all vasculitides involve some degree of constitutional symptoms, including fever, malaise, weight loss, and arthralgias. There is substantial overlap in the signs and symptoms associated with the large-, medium-, or small-vessel disorders. Practically, it is more useful to classify the vasculitides according to the pattern of organ system involvement or exposure most evident on presentation: vasculitis presenting with large-vessel occlusive symptoms, vasculitis typified by pulmonary-renal manifestations, vasculitis with characteristic cutaneous manifestations, and syndromes associated with environmental or foreign antigen exposure. This approach assists in refining the differential diagnosis for a given constellation of symptoms and directing initial therapy while awaiting the results of confirmatory tests or tissue biopsy, which are in most cases not readily available in the ED.

Table 118-5 Primary and Secondary Vasculitis: Classification and Associated Features

Predominantly Large Vessel		*Predominantly Medium Vessel*		*Predominantly Small Vessel*	
EXAMPLES	COMMON FEATURES	EXAMPLES	COMMON FEATURES	EXAMPLES	COMMON FEATURES

Vasculitis Presenting with Large-Vessel Occlusive Symptoms

Giant Cell Arteritis. Giant cell arteritis (GCA), also known as temporal arteritis, is a systemic vasculitis that affects medium-sized and large vessels. The most recognized symptoms are caused by occlusion of the superficial branches of the carotid artery, although systemic medium- and large-vessel disease involving the carotid, subclavian, aortic, vertebral, and iliac vessels may also be present. The most feared complication of GCA is irreversible visual loss, occurring in up to one third of patients.[78] Early treatment can help prevent this complication, and thus the diagnosis is an important consideration in patients older than 50 years presenting with any combination of constitutional symptoms, headache, visual changes, and jaw claudication.

The incidence of GCA has been increasing steadily during the past 20 to 40 years.[79] The syndrome is tightly coupled to age, with a mean age at onset of 70 years and a range of 50 to 90 years.[80] The incidence increases sharply after the age of 50 years, with an estimated incidence of 33 per 100,000 patients. The disease is twice as common in women than in men, and smoking increases the risk of GCA sixfold in women.

GCA is frequently associated with a spectrum of nonspecific symptoms, such as fever, weight loss, and fatigue. Common presenting complaints include headache, visual symptoms, jaw claudication, and myalgias and associated polymyalgia rheumatica.[80] Headache, the most common presenting symptom, occurs in three quarters of patients with GCA.[81] Although it is classically located in the temporal area and in association with tenderness along the superficial temporal artery, no specific pattern of headache location or severity is predictive of the temporal arteritis, and in untreated patients the headache may improve or disappear, even though active disease is still present.[80,82-84] The presence of tenderness, prominence, or beading of the superficial temporal artery on physical examination is associated with GCA, whereas the absence of any temporal artery abnormality is associated with a modest decrease in the likelihood of disease.[81] Changes in visual acuity occur as a result of occlusive arteritis of the posterior ciliary artery or less commonly retinal artery occlusion. Visual loss may occur in one or both eyes and at times be painless; interruptions in acuity may be partial or complete, transient or permanent.[78,85] The visual deficit is often profound, with 80% of patients unable to appreciate hand waving.[78] Funduscopic findings in patients with acute visual loss include optic disk pallor and edema, in keeping with ischemic optic neuritis. Complete visual loss that is present for more than a few hours is usually irreversible.[78] Diplopia may also occur as a result of ischemic ophthalmoplegia; oculomotor nerve lesions typically spare the pupil.[82]

Thoracic aortic aneurysms are 17 times more likely to occur in patients with GCA compared with age-matched controls.[86] The vertebral-basilar arteries are affected in 75 to 100% of patients, leading to signs of vertebrobasilar insufficiency, including gait disturbance, dizziness or vertigo, and vomiting.[87] The diagnosis of GCA should be considered in elders with signs of vertebrobasilar insufficiency in conjunction with constitutional symptoms and an elevated ESR.

In the presence of symptoms consistent with occlusion of superficial branches of the carotid artery, the diagnosis is usually straightforward. The American College of Rheumatology has developed a scoring system that lends equal weight to each of five diagnostic criteria (Box 118-4).[88] Patients with a score of ≤2 require temporal artery biopsy for the diagnosis to be confirmed; in patients with a score of ≥3, a biopsy adds little information beyond clinical and laboratory appraisal.[89] An ESR of ≥80 mm/hr is common, although approximately 20% of patients with an ESR of <50 mm/hr will go on to have biopsy-proven temporal arteritis. An elevated C-reactive protein level has improved sensitivity over ESR and may actually be the preferred diagnostic test, with a reported sensitivity for GCA of 97.5%.[90] The gold standard for diagnosis remains temporal artery biopsy, with established sensitivity of 90 to 95%.[91] Bilateral biopsies should be considered in patients for whom clinical suspicion is high and initial findings on biopsy are normal. The role of color duplex ultrasonography in the diagnosis of temporal arteritis remains controversial; one study showed no benefit in establishing the diagnosis when it was added to a carefully performed physical examination.[92] High-resolution magnetic resonance imaging may be used alone or as a diagnostic adjunct to biopsy in atypical or challenging cases.[93]

Box 118-4 American College of Rheumatology Classification Criteria for Giant Cell Arteritis

Age ≥ 50 years
New-onset localized headache
Temporal artery tenderness or decreased temporal artery pulse
Erythrocyte sedimentation rate ≥ 50 mm/hr
Abnormal artery biopsy specimen characterized by mononuclear infiltration or granulomatous inflammation

Modified from Hunder GG, et al: The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. Arthritis Rheum 33:1125, 1990.

Given the high stakes and morbidity associated with missed or delayed diagnosis, initiate treatment for temporal arteritis as soon as the diagnosis is considered to prevent permanent visual loss. The mainstay of treatment remains high-dose corticosteroids, initiated in the ED and continued until the diagnosis can be confirmed or excluded on subsequent biopsy. A typical initial regimen is oral prednisone 60 to 100 mg daily (or 1 mg/kg) with a temporal biopsy scheduled within 1 week of presentation. More than half of patients treated within 24 hours of presentation will achieve some recovery, compared with only 6% when treatment is delayed beyond this interval.[94] Oral corticosteroids do not alter the sensitivity of temporal artery biopsy when it is performed within 2 weeks of initiation of therapy.[95] Some authors recommend switching to intravenous corticosteroid treatment for 3 days should vision continue to deteriorate despite timely initiation of oral prednisone.[96] Acetylsalicylic acid may be useful as an adjunct to decrease ischemic complications.[97]

Takayasu's Arteritis. Takayasu's arteritis, also known as pulseless disease or occlusive thromboaortopathy, is a systemic large-vessel vasculitis of unknown etiology that primarily affects young women of Japanese and Southeast Asian descent. It is characterized by granulomatous inflammation of the aorta and its branches, leading to massive intramural fibrosis and symptoms of large-vessel stenosis, thrombosis, and aneurysm.

Takayasu's arteritis is a rare disorder worldwide, with a reported incidence of 0.2 to 2.6 cases per million in western Europe and North America, although this number is much higher in Japan.[98] The disease is eight times more common in women than in men; symptoms are first manifested between the ages of 15 and 25 years.[98] The diagnosis should be considered in women younger than 40 years who present with signs and symptoms of large-vessel occlusion, including upper limb claudication, decreased or asymmetrical pulses, and unexplained hypertension accompanied by constitutional symptoms such as fever and weight loss.

The most common presenting symptoms related to vascular occlusion are claudication (most commonly of the upper extremity, 35%), reduced or absent pulse (25%), hypertension (most often associated with renal artery stenosis, 20%), carotidynia (20%), lightheadedness (20%), and asymmetrical arm blood pressures (15%).[99] Cerebrovascular ischemia, stroke, aortic insufficiency, and visual symptoms are present in 10% of patients.[99] Approximately 80% of patients will have an identifiable bruit on physical examination, and 50% will go on to have asymmetrical

blood pressures.[99] One third of patients will have cardiac complications, including aortic insufficiency and regurgitation, myocarditis, congestive heart failure, and cardiac ischemia from coronary artery aneurysm.[99] Patients presenting after the age of 40 years or without signs of vascular occlusion pose a diagnostic challenge; only nonspecific constitutional symptoms or fever of unknown origin may initially be manifested, leading to diagnostic and therapeutic delays.

Although an elevated ESR (>80 mm/hr) is suggestive of Takayasu's arteritis, the majority of laboratory investigations are nonspecific, and the diagnosis is almost always secured on the basis of clinical assessment and diagnostic imaging. Patients younger than 40 years who present with symptoms of large-vessel occlusive disease (bruit, absent pulse, claudication) are candidates for axial imaging of the aorta and its major branches; options include CT angiography and magnetic resonance angiography, both of which have largely replaced digital subtraction angiography as the imaging method of choice.[100] Once a diagnosis of Takayasu's arteritis is made, oral corticosteroids (e.g., 0.5 to 1 mg/kg prednisone daily) are indicated and continued for 4 to 12 weeks, followed by a gradual taper. It is a self-limited disorder in 20% of patients; the remainder will go on to have a relapsing-remitting or chronic progressive course requiring long-term corticosteroids.[101] Steroid-sparing agents such as azathioprine, cyclophosphamide, and tumor necrosis factor inhibitors may be added in patients who relapse. Patients should be observed closely by a rheumatologist and vascular surgeon; those who do not respond to corticosteroids may benefit from surgical reperfusion, including bypass grafting and percutaneous transluminal angioplasty. Indications for admission include signs and symptoms of acute end-organ ischemia, aortic insufficiency, myocarditis, and decompensated congestive heart failure. The most common causes of death are congestive heart failure, renal failure, and infectious complications.[102]

Vasculitis Typified by Pulmonary-Renal Manifestations

Vasculitis syndromes in this category are characterized by a predominance of pulmonary and renal manifestations, including dyspnea, cough, pulmonary infiltrates, and renal insufficiency secondary to glomerulonephritis, in addition to a variety of systemic symptoms. Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome share a strong association with the presence of antineutrophil cytoplasmic antibodies (ANCA) of various subtypes, including cytoplasmic staining (c-ANCA) and perinuclear staining (p-ANCA), measured in the blood by enzyme-linked immunosorbent assay or direct immunofluorescence.[103] Whether ANCA are involved in pathogenesis or are simply markers of disease is unclear. The absence of ANCA does not rule out an ANCA-associated vasculitis syndrome because between 20 and 50% will have negative assays.[103]

A comparison of the common presenting features of Wegener's granulomatosis, microscopic polyangiitis, Goodpasture's syndrome, and Churg-Strauss syndrome is shown in Table 118-6.

Wegener's Granulomatosis. Wegener's granulomatosis is a c-ANCA–associated systemic necrotizing vasculitis of small and medium-sized blood vessels with a predilection for the upper and lower respiratory tracts and kidneys. The constellation of upper respiratory, pulmonary, and renal disease in patients with constitutional symptoms suggests Wegener's granulomatosis. In the absence of pulmonary or renal symptoms, the diagnosis is extremely challenging and often missed. Wegener's granulomatosis is more common in white individuals but otherwise shows no specific pattern of distribution for age, sex, or geography. The annual incidence is estimated to be 3 per 100,000 people.[104]

Constitutional symptoms including fever, malaise, and weight loss are often evident on initial presentation. Upper airway disease is the most common presenting symptom of Wegener's granulomatosis, with 90% of patients developing upper respiratory tract symptoms in some form.[105] Upper airway manifestations include serous otitis media with or without suppurative infection, hearing loss, sinusitis, nasal mucosal ulcerations and septal perforation, epistaxis, and laryngotracheal disease.[105] Subglottic stenosis is the most common laryngotracheal lesion, present in about 16% of patients, the severity of which can range in presentation from mild dyspnea to acute airway obstruction and respiratory extremis.[105] Nearly 50% of pediatric and adolescent patients will have some degree of subglottic stenosis, with implications for airway management. Lower respiratory symptoms include cough, dyspnea, pleuritis, and hemoptysis. Radiographic studies may demonstrate pulmonary infiltrates and nodules, although the severity of radiographic findings does not always correlate well with symptom severity (Fig. 118-6). A minority of patients present with diffuse alveolar hemorrhage, which has an associated mortality of approximately 50%.[106] Renal embarrassment tends to be a later finding, developing in a subset of patients with generalized disease. Once progressive renal failure has developed, it may evolve rapidly during days to weeks, leading to end-stage renal disease that, if left

www.ketabpezeshki.com 66485457-66963820

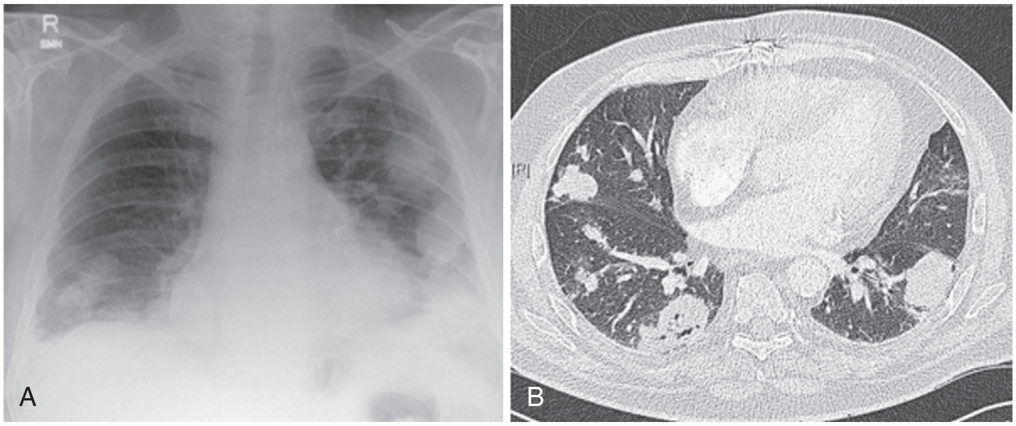

Figure 118-6. **A,** Multiple intrapulmonary nodules on a chest radiograph of a patient with Wegener's granulomatosis. **B,** Pulmonary nodules seen on CT imaging. (From Adam A, Dixon AK: Grainger & Allison's Diagnostic Radiology, 5th ed. Philadelphia, Churchill Livingstone, 2008.)

untreated, is associated with a mean survival of 5 months.[107] Chronic renal insufficiency can develop despite appropriate treatment, with a subset of patients requiring dialysis or renal transplantation.[105]

The list of associated symptoms in Wegener's granulomatosis is myriad and speaks to the systemic nature of the disease. Ophthalmologic (scleritis, episcleritis, uveitis), cutaneous (palpable purpura, subcutaneous nodules, ulcers), neurologic (mononeuropathy and polyneuropathy, cerebral vasculitis, cerebral hemorrhage, or thrombosis), and cardiac (pericarditis, myocarditis) disease may be present to varied degrees.

ED management is directed first toward life-threatening pulmonary hemorrhage and sequelae from acute or decompensated chronic renal insufficiency. The combination of diffuse alveolar hemorrhage and subglottic stenosis represents a "double hit" difficult airway, requiring extreme caution during endotracheal intubation. Although a large endotracheal tube is preferred for the management of massive hemoptysis, selection of a smaller tube size may be required to bypass a narrow subglottic corridor. Fiberoptic intubation through an intubating laryngeal mask airway has been advocated.[108] Combination therapy with corticosteroids and cyclophosphamide is considered the current standard of care for patients with acute flares and has dramatically changed the disease prognosis. Before the use of steroids, 1-year mortality approached 90%; combination therapy with corticosteroids and cyclophosphamide has improved the 5-year survival to nearly 90%, with the majority of patients achieving remission.[105,109,110] Methotrexate plus corticosteroids may be used instead of cyclophosphamide in less severe presentations involving systemic disease.[110] Patients presenting with new or suspected Wegener's granulomatosis and those with severe disease require admission for high-dose intravenous dual-agent therapy. The diagnosis is typically confirmed by open lung biopsy.[105,111] Patients who present with new respiratory symptoms or infiltrates on the chest film should probably be hospitalized and treated for infection until it is proven otherwise, given the morbidity associated with pneumonia in an immunocompromised host.

Goodpasture's Syndrome. Goodpasture's syndrome describes the clinical triad of glomerulonephritis, pulmonary hemorrhage, and circulating anti–glomerular basement membrane (GBM) antibodies. The syndrome is distinct from Goodpasture's disease, which consists of glomerulonephritis and anti-GBM antibodies without pulmonary hemorrhage. Goodpasture's syndrome is not associated with ANCA; anti-GBM autoantibodies target type IV collagen found in the basement membranes of glomeruli and pulmonary alveoli, causing autoimmune damage through a type II hypersensitivity reaction.[112] The disease can affect people of all ages, with white individuals more commonly affected.[112] The incidence is bimodal; one peak occurs in 20- to 30-year-old men and a second in 50- to 70-year-olds of both sexes. The incidence is believed to be about 1 case per 2 million individuals.[113]

There is substantial variation in the presentation of patients with anti-GBM disease. Pulmonary or renal symptoms may exist alone or in combination, although the two are most often present together. Fever, malaise, and weight loss are common early symptoms. Pulmonary symptoms range from dyspnea and cough to hypoxemia and frank pulmonary hemorrhage, which can be massive and life-threatening. Chest radiographic findings may be normal or demonstrate hilar pulmonary infiltrates sparing the apices and costophrenic angles. Renal failure can be insidious or be manifested as rapidly progressive glomerulonephritis with acute kidney injury and volume overload. Urinalysis shows characteristic signs of acute glomerulonephritis, including hematuria, proteinuria, and red cell casts. Definitive diagnosis is made by lung or renal biopsy demonstrating linear deposition of anti-GBM antibodies in the alveolar or glomerular basement membranes, respectively.[112]

Initial management of patients with massive pulmonary hemorrhage is focused on securing a definitive airway and addressing hemodynamic instability. Bronchoscopy or chest radiography can be used to identify the source of hemorrhage, and selective intubation of the contralateral mainstem bronchus or use of a double-lumen endotracheal tube and ventilating with the affected lung in the dependent position may improve oxygenation. High-dose methylprednisone (10-15 mg/kg) and cyclophosphamide are the mainstays of immune suppressive therapy. Therapeutic plasma exchange can be used to decrease the level of circulating anti-GBM antibodies during acute presentations.[114] Patients who have end-stage renal disease may be candidates for renal transplantation, assuming anti-GBM antibodies are undetectable with treatment, else the disease may recur in the transplanted graft.[115] The prognosis has improved in recent years owing in part to the more aggressive use of therapeutic plasma exchange.

Microscopic Polyangiitis. Microscopic polyangiitis was first recognized in a subset of polyarteritis nodosa patients who presented with segmental glomerulonephritis.[116] This systemic small-vessel vasculitis is the most common cause of the pulmonary-renal syndrome, leading to renal failure and pulmonary hemorrhage, the two most clinically relevant features of microscopic polyangiitis. The disease affects men and women equally and typically is manifested in the fourth or fifth decade of life, although it may occur at virtually any age.[117] The annual incidence in the United States is approximately 3.8 cases per 1 million population. The characteristic presentation of rapidly progressive renal failure in

www.ketabpezeshki.com 66485457-66963820

the context of pulmonary alveolar hemorrhage and systemic symptoms occurs in the minority of patients; in many cases the disease presentation is protean, consisting largely of renal insufficiency and constitutional symptoms such as fever, weight loss, and malaise.

Glomerulonephritis with subsequent renal insufficiency is a nearly universal finding in microscopic polyangiitis, and renal failure can be acute and rapidly progressive or chronic and insidious; 25 to 45% of patients require dialysis at some point during the course of the disease.[118,119] The specific renal disease is that of necrotizing glomerulonephritis including elevated serum creatinine and blood urea nitrogen concentrations and a urinalysis demonstrating red cell casts, hematuria, and proteinuria. Pulmonary disease is present in up to 50% of patients, and diffuse alveolar hemorrhage is present in about 12%.[117] Respiratory symptoms range from cough, dyspnea, and pulmonary fibrosis to massive diffuse alveolar hemorrhage requiring active and aggressive resuscitation and airway management. Peripheral neuropathy in the form of mononeuritis multiplex is present in up to 60% of cases. Skin manifestations are common, with about 50% of patients having palpable purpura.[119,120]

It can be difficult to distinguish microscopic polyangiitis from other ANCA-positive syndromes, including Wegener's granulomatosis and Churg-Strauss syndrome, on clinical grounds alone. Microscopic polyangiitis and Wegener's granulomatosis probably exist on a spectrum of illness, and it is usually not required to distinguish between the two in the emergency setting to direct management. The diagnosis is typically secured by tissue biopsy of the lung, kidney, or skin, with demonstration of pulmonary capillaritis, necrotizing glomerulonephritis, or leukoclastic vasculitis, respectively.[120] The priority in patients presenting with acute or decompensated chronic renal insufficiency is to identify and to manage immediate threats, including volume overload, electrolyte disturbances, and refractory acidosis. Admission for renal optimization, intravenous administration of steroids, and possibly dialysis is often required. Airway management is the priority in those presenting with diffuse alveolar hemorrhage, and a difficult intubation should be anticipated. In the presence of serious pulmonary and renal disease, a combination of high-dose glucocorticoid and cyclophosphamide is the treatment of choice, demonstrating superiority over glucocorticoid alone.[121] Mortality in microscopic polyangiitis is approximately 30% during 7 years; morbidity and mortality are the highest in patients with a heavy burden of renal, cardiovascular, or neurologic disease.[121] Plasmapheresis and IVIG are options for refractory cases. Remission is much more common than in Wegener's granulomatosis and is achieved in about 90% of patients, although up to one third will experience flares after remission.[122]

Churg-Strauss Syndrome. Churg-Strauss syndrome, also known as allergic granulomatosis, is an autoimmune vasculitis of medium-sized and small vessels associated with asthma and eosinophilia. The etiology is unknown, although there is a strong association with allergy and atopy. The mean age at onset is typically in the fourth decade of life; men are affected more often than women are. The annual incidence is approximately 2.4 cases per 1 million individuals.[123]

Patients with Churg-Strauss syndrome may present in three distinct stages, although there may be considerable overlap and variance. Most patients with Churg-Strauss syndrome have asthma and allergic rhinitis several years before the onset of vasculitis. Over time, asthma symptoms may actually improve as the vasculitic stage of the disease sets in.[120] The pattern of medium-sized vessels involved determines the clinical picture of the vasculitic phase, although pulmonary, renal, and neurologic symptoms are common. Pulmonary infiltrates, pleural effusion, and alveolar hemorrhage may be seen during the prodromal or vasculitic stage.[120] Renal involvement is less common compared with other ANCA-positive vasculitis syndromes and may preferentially affect the lower urinary tract and prostate gland, leading to obstructive uropathy.[124] Cardiac manifestations, including restrictive pericarditis and cardiomyopathy leading to congestive heart failure, are more common in Churg-Strauss syndrome compared with Wegener's granulomatosis and microscopic polyangiitis.[125] Mononeuritis multiplex, asymmetrical neuropathy, and cranial neuropathies are the most frequently observed neurologic symptoms, seen in up to 80% of patients.[123] Gastrointestinal symptoms include infarction, perforation, and hemorrhage secondary to infiltration of the small bowel or stomach.

Laboratory investigation demonstrates a persistently elevated eosinophil count (>1500 cells/mm^3), although this does not correlate well with the presence of active disease. Myeloperoxidase-ANCA antibodies are seen in about 40% of cases.[126] Pulmonary infiltrates are typically patchy and transient in nature (Löffler's syndrome). The diagnosis of Churg-Strauss syndrome is made by a combination of clinical and histologic features; evidence of necrotizing vasculitis or extravascular granulomas on skin or lung biopsy in conjunction with eosinophilia, asthma, and allergy is highly suggestive of the disease.

Corticosteroids are the mainstay of treatment, although immunomodulating agents such as cyclophosphamide may be added to achieve remission in cases complicated by cardiac, renal, or gastrointestinal involvement.[110,127] The overall survival for patients with Churg-Strauss syndrome approaches 80%, with an increased relative risk of death predicted by the presence of renal and gastrointestinal symptoms.[128]

Vasculitis with Characteristic Cutaneous Manifestations

Cutaneous vasculitis involves inflammation of the blood vessels of the skin. The diseases listed here are associated with cutaneous manifestations that are often characteristic and an important element of disease recognition in the ED. Constitutional signs and symptoms of systemic multisystem disease may also be present.

Erythema Nodosum. Erythema nodosum, a vasculitis of the venules and veins of the skin, is characterized by tender, subcutaneous nodules on the tibial surfaces of the lower legs. Erythema nodosum is presumed to be a hypersensitivity response to systemic diseases or drug therapy, although no clear precipitant can be identified in 30 to 50% of cases.[129] Peak incidence occurs in the spring or fall months among 18- to 34-year-olds, with a male-to-female ratio of approximately 1:4.

The prodromal stage of erythema nodosum consists of nonspecific constitutional symptoms, fever, malaise, and myalgias. The distribution of subcutaneous nodules favors the lower extremities, although lesions may be appreciated on the forearm, trunk, and thigh (Fig. 118-7). The nodules tend to be erythematous, well circumscribed, and exquisitely tender to touch and develop a blue hue as they resolve. Arthralgias may be present in conjunction with or before the cutaneous eruption.

Viral upper respiratory tract infections, streptococcal infection, tuberculosis, and sarcoidosis are common precipitants. Drugs associated with erythema nodosum include penicillins, sulfonamides, oral contraceptive medication, and phenytoin.[129] Less common associations include autoimmune conditions, such as inflammatory bowel disease and SLE; histoplasmosis; *Yersinia, Salmonella,* and *Chlamydia* infections; coccidioidomycosis; and psittacosis.

Management of erythema nodosum is generally supportive and directed toward symptom control and treatment or elimination of the underlying cause. Cutaneous nodules secondary to infection resolve within 6 to 7 weeks; in contrast, 30% of idiopathic cases may persist beyond 6 months. NSAIDs may be useful for

control of arthralgias; corticosteroids and colchicine are reserved for the management of protracted or refractory disease.

Henoch-Schönlein Purpura. Henoch-Schönlein purpura is a small-vessel vasculitis characterized by palpable purpura and gastrointestinal and renal manifestations associated with immunoglobulin A immune complex deposition in blood vessels. The 1990 American College of Rheumatology criteria for Henoch-Schönlein purpura include the presence of two or more of the following: age at onset younger than 20 years, palpable purpura, bowel angina, and vessel wall granulocytes on biopsy (sensitivity of 87.1%, specificity of 87.7%).[130] Although the disease can affect adults, it is most commonly seen in children younger than 5 years.

Henoch-Schönlein purpura usually is manifested 1 to 2 weeks after a viral upper respiratory tract infection with a triad of palpable purpura, arthralgias, and abdominal pain. Purpuric lesions cluster in dependent regions with a predilection for the legs and buttocks (Fig. 118-8). Colicky abdominal pain and bloody stools can occur secondary to gastrointestinal vasculitis. A rare complication of Henoch-Schönlein purpura in children is enteroenteral intussusception (ileoileal, jejunojejunal, jejunoileal), which may be associated with severe abdominal pain, lethargy, bloody diarrhea, and signs of obstruction or perforation.[131] Glomerulonephritis is typically mild and may be manifested as hematuria, red cell casts on urinalysis, and azotemia.

Management in mild disease is generally supportive, and symptoms can intermittently recur for several weeks. NSAIDs control arthralgias in most cases but are avoided if renal impairment is present. Glomerulonephritis is treated more aggressively, with a combination of corticosteroids and cyclophosphamide, azathioprine, or mycophenolate mofetil, and generally demonstrates full resolution with time. Enteroenteral intussusception can be difficult to diagnose with standard approaches (ultrasonography, air-contrast enema), and if the index of suspicion is high, patients should be assessed by a pediatric general surgeon.

Polyarteritis Nodosa. Polyarteritis nodosa is a necrotizing vasculitis of unknown etiology affecting small and medium-sized blood vessels. The disease can involve multiple systems, most commonly the skin, nervous system, and gastrointestinal tract. Necrosis occurs preferentially at arterial bifurcations and branch sites, leading to microaneurysm formation, thrombosis, emboli, organ ischemia, and infarction.[132] Polyarteritis nodosa affects men about twice as often as women, and onset occurs at any age, although the peak is typically the fourth to sixth decade of life. Annual incidence is between 2 and 9 cases per 1 million individuals.[133] Whereas the initial presentation can be nonspecific, the combination of cutaneous lesions and adult-onset hypertension with evidence of systemic illness suggests polyarteritis nodosa.

Cutaneous manifestations occur in one third of patients.[134] Palpable purpura with or without ulceration is recognized in the fingers, ankles, malleoli, and pretibial areas. Digital cyanosis may be seen secondary to ischemia. Splinter hemorrhages and livedo reticularis may also be observed. Renovascular arteritis can cause hypertension, which may at times be severe. Peripheral neuropathies in the form of mononeuritis multiplex or polyneuropathy are present in up to 50% of patients. Mesenteric vasculitis can produce abdominal angina and in rare cases lead to frank mesenteric ischemia, infarction, and perforation, often with devastating consequences.

Treatment generally begins with a corticosteroid (e.g., prednisone 1 mg/kg), and a second immunosuppressive agent is added for severe or extensive disease. Abdominal catastrophes may require surgical intervention; prognosis in these cases is poor. Polyarteritis nodosa is almost always fatal if it is left untreated, although the prognosis has been much improved with the use of

systemic corticosteroids. In a prospective study, the presence of two or more prognostic factors (azotemia, proteinuria, cardiomyopathy, gastrointestinal involvement, or neurologic signs) predicted a 5-year mortality of 46%; if none was present, the 5-year mortality was 12%.[128]

Behçet's Disease. Behçet's disease is a complex, chronic small-vessel vasculitis that may affect the mucocutaneous, ocular, cardiovascular, renal, gastrointestinal, pulmonary, urologic, musculoskeletal, and central nervous systems. Early descriptions of the disease date to the time of Hippocrates and the third book of endemic diseases.[135] The disease is defined by the presence of aphthous oral ulcers plus two or more of the following: genital aphthae; cutaneous lesions; and neurologic, oral, or rheumatologic manifestations. The exact pathogenesis remains unknown. Behçet's disease is found worldwide, with the highest prevalence in Turkey, Japan, the Middle East, and Mediterranean regions. The disease affects people of all ages, although patients often first present in the second or third decade of life.[136] The male-to-female ratio varies somewhat according to geography; women are more commonly affected than men in northern Europe and the United States, with an estimated prevalence in these regions of about 1 in 150,000 individuals.[137,138]

The triad of recurrent oral aphthous ulcers, genital ulcers, and uveitis in young adults is highly suggestive of Behçet's disease. Oral aphthous ulcers are the defining characteristic of the disease (Fig. 118-9). The lesions are typically found on the tongue, lips, buccal mucosa, and gingiva; the tonsils, palate, and pharynx are less commonly affected. The ulcers are painful, have a yellow, necrotic base, and may appear alone or in crops of three to ten. Genital ulcers appear on the scrotum and penis in men and the vulva or vaginal mucosa in women. Skin lesions include erythema nodosum–like subcutaneous nodules, pyoderma gangrenosum, cutaneous thrombophlebitis, and pustular acne-like folliculitis.[139] Ocular symptoms are common and constitute a major source of morbidity in Behçet's disease. Findings may include uveitis, iritis, and optic neuritis. Hypopyon, once considered a characteristic feature of the disease, is uncommon. Visual symptoms may be bilateral or unilateral and can occasionally lead to permanent vision loss. Neurologic manifestations include brainstem and corticospinal tract syndromes (neuro-Behçet's), aseptic meningoencephalitis, increased intracranial pressure, and cerebral sinus thrombosis complicated by optic nerve ischemia and atrophy.[140] Gastrointestinal ulcers can cause obstruction or ileocecal perforation.[141] Inflammatory oligoarthritis of the ankles, knees, elbows, and wrists is present in 40 to 60% of patients.[137]

The diagnosis of Behçet's disease is made primarily on clinical grounds. The appearance of genital lesions can be ambiguous, and other causes of painful genital ulcers need to be ruled out. Oral and genital ulcerations are often managed successfully with a topical steroid. Management of severe mucocutaneous disease involves systemic corticosteroids (e.g., prednisone, 1 mg/kg), low-dose thalidomide, or methotrexate.[142] Treatment of systemic disease may be accomplished with a corticosteroid alone or in combination with cyclophosphamide or azathioprine.[137] Ocular manifestations, including uveitis, are usually managed with prednisone plus azathioprine and require a rapid referral to an ophthalmologist. The presence of cerebral venous sinus thrombosis is an indication for immediate heparinization. Behçet's disease often has a complicated and protracted course, with morbidity related primarily to ophthalmologic complications. Death can occur from neurologic, cardiovascular, and gastrointestinal sequelae or from complications related to long-term immunosuppressive therapy.

Vasculitis Associated with Environmental or Foreign Antigen Exposure

Vasculitis Caused by Cocaine Adulterated with Levamisole. Levamisole is an immune-modulating agent that has been used to treat autoimmune disorders, various forms of cancer, and the nephrotic syndrome. The drug has been withdrawn from the U.S. drug market owing to the frequency and severity of side effects, including antibody-mediated agranulocytosis and autoimmune vasculitis. Since 2005, the incidence of cocaine cut with levamisole (added at the source of supply to add bulk and weight to the raw product) has been increasing, and some 70% of cocaine seized at U.S. borders contains levamisole to varying degrees.[143] Levamisole is not detected by routine blood and urine toxicology testing, and specialized testing with gas chromatography or mass spectrometry is of limited clinical utility given the short half-life of the drug (5.6 hours); it is unlikely to be detected in the plasma or urine beyond 24 to 72 hours after the last exposure.[143]

The rash associated with levamisole involves tender palpable purpuric plaques with a predilection for the cheeks, nose, and earlobes (Fig. 118-10). Treatment is typically supportive; spontaneous resolution occurs with discontinuation of the offending agent. The agranulocytosis associated with levamisole is transient

Table 118-7 Summary of Buerger's Disease (Thromboangiitis Obliterans), Serum Sickness, and Hypersensitivity Vasculitis

	BUERGER'S DISEASE	SERUM SICKNESS	HYPERSENSITIVITY VASCULITIS
Pathophysiology	Small and medium-sized arteries and veins of the extremities	Immune complex deposition in blood vessel walls	Small vessel
Associated exposures	Heavy cigarette smoking Cold exposure	Foreign protein or serum Penicillin-based antimicrobials Sulfa drugs NSAIDs	β-Lactam antibiotics NSAIDs Diuretics
Common symptoms	Pain, paresthesias Claudication Rest pain	Fever, arthralgias, and diffuse lymphadenopathy Pruritus, skin lesions	Typically confined to the skin (vs. serum sickness)
Physical examination findings	Poorly healing wounds, ulcerations Splinter hemorrhages Digital ischemia and necrosis Distal-to-proximal progression	Urticaria Purpuric skin lesions Scarlatiniform rash Erythema multiforme Azotemia, proteinuria Myocarditis, pericarditis	Palpable purpura in dependent regions, including legs and buttocks Urticarial vasculitis Livedo reticularis Skin nodules and ulcers
Diagnosis	Angiography: demonstrates "corkscrew" pattern of collateral vessels; rule out other causes of ischemia	Clinical	Clinical
Management and outcome	Smoking cessation Meticulous wound care Protection from trauma and thermal injury	Supportive Systemic corticosteroids for severe disease Recovery generally within 4-6 weeks	Supportive Systemic corticosteroids for severe disease
Comments	Up to 50% of patients who continue to smoke will require amputation	Incidence has decreased with modern immunization programs and the use of products derived from human serum	In theory, any medication can cause a hypersensitivity vasculitis syndrome

NSAIDs, nonsteroidal anti-inflammatory drugs.

and fully reversible within a week to 10 days after discontinuation of the offending agent. Patients may present with asymptomatic agranulocytosis detected on routine blood work or with fever, sepsis, or signs of overwhelming infection. Febrile patients are treated aggressively with broad-spectrum antibiotics and a septic workup directed at the likely source of infection, similar to febrile neutropenia associated with chemotherapy. Afebrile patients are also often admitted for investigation and observation until their neutrophil count recovers.

Cryoglobulinemic Vasculitis. Cryoglobulins are immunoglobulins that precipitate from serum at cold temperatures.[144] Damage to small and medium-sized blood vessels occurs when cryoglobulins bind to circulating antigens and deposit in vessel walls, prompting a complement-mediated inflammatory reaction and cryoglobulinemic vasculitis.

Three types of cryoglobulinemic vasculitis syndromes have been identified. Type I is associated with Waldenström's macroglobulinemia and multiple myeloma and produces a syndrome of hyperviscosity with symptoms of presyncope, altered mental status, and stroke. Types II and III are known as the mixed cryoglobulinemias and represent 80% of recognized cryoglobulinemic syndromes. There is a strong association between these subtypes and hepatitis C, Sjögren's syndrome, and SLE. The mixed cryoglobulinemias are manifested with a triad of purpura, arthralgias, and myalgias along with glomerulonephropathy and vasculitic peripheral neuropathy. Purpuric lesions are typically multiple and confluent and appear preferentially in dependent areas and the lower extremities in particular.[144] Renal failure is the most serious consequence of cryoglobulinemia and is present in 20 to 60% of patients.[145]

The diagnosis is based on the presence of serum cryoglobulins accompanied by typical clinical features; the most salient elements of the differential diagnosis include SLE and Henoch-Schönlein purpura . Skin biopsy can be helpful in confirming the diagnosis. Management involves identification and treatment of associated diseases, such as hepatitis C and multiple myeloma. Low-dose corticosteroids are helpful when systemic symptoms are present but should be avoided while antiviral therapy is being initiated. Plasmapheresis may be useful in life-threatening cases related to cryoprecipitation or serum hyperviscosity.

Features associated with Buerger's disease, serum sickness, and hypersensitivity vasculitis are outlined in Table 118-7.

KEY CONCEPTS

Systemic Lupus Erythematosus

- SLE may affect any organ system. Thus, a fundamental understanding of the disease is required to tailor the differential diagnosis and workup.
- A 50-fold increased risk of CAD and up to a 30-fold increased risk of venous thromboembolism in patients with SLE prompt aggressive chest pain workups in the ED, even in young women.
- An elevated C-reactive protein level is more closely linked to infection in SLE patients and is not reflective of SLE disease activity. An isolated elevated PTT in a patient with SLE prompts consideration for antiphospholipid antibody carrier state and, if there is a history of thrombosis, antiphospholipid syndrome.
- Steroids are the mainstay for management of the majority of conditions that are associated with increased SLE disease activity, including musculoskeletal, cutaneous, renal, pleural, and pericardial disease.
- Antiphospholipid syndrome is common in patients with SLE and carries with it a risk of venous (typically deep venous thrombosis or pulmonary embolism) and arterial (most commonly stroke) thrombosis.

www.ketabpezeshki.com 66485457-66963820

- Consultation with a rheumatologist may be helpful in diagnostic, management, and disposition decisions for patients with SLE.

Vasculitides

- Vasculitis syndromes should be considered in the presence of systemic symptoms such as fever, malaise, and weight loss plus pulmonary, renal, or cutaneous manifestations.
- Massive hemoptysis and acute renal failure can occur in Wegener's granulomatosis, Goodpasture's disease, microscopic polyangiitis, and Churg-Strauss syndrome. Tracheal stenosis may be present in Wegener's granulomatosis, further complicating airway management.
- Many patients with established vasculitis are receiving high-dose or combination immune suppressive therapy, making them vulnerable to opportunistic infections and overwhelming sepsis.

Chapter 119

Allergy, Hypersensitivity, Angioedema, and Anaphylaxis

T. Paul Tran and Robert L. Muelleman

PERSPECTIVE

The human immune system is an assemblage of cellular and humoral components working together in a highly complex, coordinated, and elegant fashion to achieve the primary goal of protecting the human host (*self*) from harmful offenders (*nonself*). Exposure to *danger* signals activates the various immune mechanisms to bring about immune responses aimed at neutralizing the dangerous nonself while preserving self.[1] The immune system can, however, overreact to otherwise harmless nonself agents, producing inappropriate responses that are harmful to the host, thereby giving rise to allergy or allergic diseases. These hypersensitivity reactions are manifested in clinical symptoms ranging from mildly inconvenient to debilitating to fatal. For practical purposes, the term *allergy* is used in this chapter to refer to mast cell–mediated hypersensitivity reactions. For most allergic diseases to occur, predisposed individuals need to be exposed to allergens through a process called *sensitization*. Substances that elicit an allergic reaction are referred to as *allergens,* and those that elicit an antibody response (activated by B- and T-cell receptors) are called *antigens*.

In this allergic continuum, there are several important allergic syndromes frequently encountered in the emergency department (ED). *Urticaria* is a common allergic reaction to foods, drugs, or physical stimuli and is clinically characterized by a red itchy rash. *Angioedema* is the other important allergic syndrome, mediated by either an allergic mechanism in response to exposure to foods, drugs, or physical stimuli or a nonallergic mechanism (e.g., angiotensin-converting enzyme [ACE] inhibitor). Angioedema is characterized by swelling of the subcutaneous tissues, which can cause airway difficulty if the larynx is involved. At the other extreme of this allergic continuum is *anaphylaxis,* a life-threatening systemic allergic reaction characterized by acute onset and multiorgan involvement. The term *anaphylaxis* is derived from Greek (*ana,* against; *phylax,* guard or protect), meaning "against protection." Mechanistically, anaphylaxis is a type I hypersensitivity reaction (allergic), mediated by immunoglobulin E (IgE). In its most common form, anaphylaxis is precipitated by exposure to allergens in previously sensitized individuals. Timely recognition of the syndrome and proper care are essential to bring about beneficial outcomes for patients with anaphylaxis.

The term *anaphylactoid reaction* refers to a syndrome clinically similar to anaphylaxis that is not mediated by IgE. Its clinical presentation and treatment are identical to those of anaphylaxis. Anaphylactoid reactions appear to result from direct degranulation of mast cells (and basophils) and may follow a single, first-time exposure to certain inciting agents. In this chapter, we use the term anaphylaxis to refer to both IgE- and non–IgE-mediated reactions, obviating the need for the term anaphylactoid reaction.

Epidemiology and Risk Factors

The incidence of anaphylaxis has not been determined with certainty, but recent evidence suggests that it is increasing.[2] There are approximately 100,000 attacks of anaphylaxis in the United States per year, of which approximately 60,000 are first-time events and 1000 to 1500 are fatal.[3]

Factors affecting the incidence of anaphylaxis include time of the year, age, female sex (adults), higher socioeconomic status, northern locations, route of allergen exposure, and history of atopy (Box 119-1).[2,4] Anaphylactic reactions seem to be more common in the summer and early fall, coincident with the outdoor season; in people of higher socioeconomic status; and in people with a history of atopy. In general, anaphylaxis is more common in adults, but in particular, it is more common in women older than 30 years and in boys younger than 16 years. The dose, frequency, duration, and route of administration of a drug also affect the tendency to develop an anaphylactic reaction; the parenteral route is more likely than the oral route to lead to an anaphylactic reaction. One interesting aspect of drug-related anaphylaxis is the constancy of administration. An anaphylactic reaction may not occur in an otherwise susceptible patient as long as a drug is administered at regular intervals. The same patient may, however, experience an anaphylactic reaction if the drug is resumed after an interruption of therapy.[5]

Risk factors for increased severity and mortality of an anaphylaxis reaction include having a recent episode of anaphylaxis, extremes of age, presence of atopy or cardiopulmonary conditions, taking medications that may influence timely recognition of the symptoms or impede the treatment of anaphylaxis, and rapid onset of symptoms after exposure (see Box 119-1).[2,6] The more rapid an anaphylaxis reaction is after an exposure, the more likely it is to be severe and potentially fatal. Whereas anaphylaxis in an infant is a rare event, timely recognition of an anaphylactic reaction in an infant can be difficult because signs of anaphylaxis, such as flushing, vomiting and diarrhea, lethargy, and dystonia after feeding, can be overlooked as minor reactions.[7] Elders, on the other hand, tend to have worse outcomes in anaphylaxis because of their comorbid conditions, notably heart failure, ischemic heart disease, hypertension, and obstructive lung diseases. A history of asthma and atopy is associated with a more severe or fatal anaphylactic reaction. This is particularly true when the allergen is administered by the mucosal route (e.g., food). Atopy does not, however, seem to be a risk factor when the allergen is administered parenterally (e.g., penicillin). Patients with psychiatric disorders and individuals taking medications and drugs that may impede prompt recognition of an anaphylaxis reaction are also at increased risks (e.g., recreational drugs, alcohol, tranquilizers, and hypnotics). In addition, two classes of medications concurrently

www.ketabpezeshki.com 66485457-66963820

Box 119-1 Risk Factors for Having Anaphylaxis and Increased Anaphylaxis Severity and Mortality

Risk Factors for Having Anaphylaxis

Age and sex
- Males < 16 years, females > 30 years

Route of administration
- Parenteral > oral

Higher social economic status

Time of the year
- Summer and fall (the outdoor seasons)

History of atopy

Risk Factors for Increased Anaphylaxis Severity and Mortality

Extremes of age
- Very young (under-recognition)
- Elderly (increased risks of mortality from treatment and venom-induced anaphylaxis)

Comorbid conditions
- Cardiovascular disease (heart failure, ischemic heart disease, hypertension)
- Pulmonary disease (asthma, obstructive airway disease, acute infection)

Others
- Concurrent use of beta-blockers and angiotensin-converting enzyme inhibitors
- Concurrent use of cognition-impairing drugs (e.g., alcohol, recreational drugs, sedatives, tranquilizers)
- Recent anaphylaxis episode

Modified from Lieberman P: Anaphylaxis. Med Clin North Am 90:77-95, 2006, viii; and Simons FE: Anaphylaxis. J Allergy Clin Immunol 125(Suppl 2):S161-S181, 2010.

taken by patients may increase their risks of anaphylaxis severity. ACE inhibitors can cause an accumulation of kinins and bradykinin and thus can exacerbate the angioedema in anaphylaxis. Beta-blockers can oppose the actions of adrenergic agents used in anaphylaxis treatment, potentially leading to protracted hypotension.

Triggers for Anaphylaxis

Virtually any agent that is capable of activating mast cells (or basophils) can potentially precipitate an anaphylactic reaction. In approximately one third of the cases, however, an inciting agent cannot be identified.[8] When a cause can be determined, foods, medications, and insect stings are the most common causes of anaphylactic reactions. Box 119-2 lists most common agents by their proposed immunologic mechanism.[9] Reactions without identifiable causative agents are classified as physically induced or iatrogenic anaphylaxis.

Foods

Foods are the major identifiable causative agents, accounting for approximately one third of the cases of anaphylaxis.[8] A variety of foods have been identified, ranging from the well-known (nuts, shellfish, and eggs) to the obscure (chamomile tea, which may have cross-reactivity with ragweed). Cow's milk, egg, peanut, soy, wheat, fish, shellfish, and tree nuts are foods that most commonly cause anaphylaxis. Even for a person with a known history of food allergy, it may be difficult to avoid foods that may cause allergic reactions because their identity may be obscured in processing (e.g., consuming wine contaminated with Hymenoptera venom).[10] Because allergenic foods are first absorbed transmucosally, symptoms of food anaphylaxis may first appear localized to the upper airway of the respiratory tract. When anaphylactic allergens are administered parenterally, symptoms of anaphylaxis tend to be more cardiovascular and systemic. Allergic reactions to foodstuffs are more common in children, with incidence ranging from 0.3 to 7.5%.[11]

Box 119-2 Etiologic Agents Causing Anaphylaxis by Immunologic Mechanisms

IgE-Dependent Mechanism

Food: egg, peanut, tree nut, milk, fruits, shellfish, shrimp, other crustaceans
Antibiotics: penicillins, cephalosporins, sulfonamides, nitrofurantoin, tetracycline, streptomycin
Insect stings: Hymenoptera venoms, fire ant stings
Natural rubber latex
Hormones: insulin, methylprednisolone, parathormone, estradiol, progesterone, corticotropin
Enzymes: trypsin, streptokinase, chymotrypsin, chymopapain, L-asparaginase
Other therapeutics: NSAIDs (some are IgE independent), methylparaben, human diploid cell rabies vaccine, egg-based vaccines (measles, mumps, rubella), vasopressin, antilymphocyte globulin, heterologous and human sera, local anesthetics (mostly ester family, procaine, tetracaine, benzocaine)
Seminal fluid

IgE-Independent Mechanism (direct mast cell degranulation)

Radiocontrast media
Aspirin and NSAIDs (arachidonic acid metabolism)
Alcohol, opiates, protamine, polysaccharides (some are IgE mediated), curare, D-tubocurarine
Certain food colorants and additives

Immune Complex Mediated

Whole blood (transfusion reaction to formed elements), immunoglobulins

Physical Factors

Exercise
Heat or cold
Sunlight
Ultraviolet radiation

Miscellaneous

Factitious
Undifferentiated somatoform idiopathic anaphylaxis
Idiopathic

Modified from Kemp SF, Lockey RF: Anaphylaxis: A review of causes and mechanisms. J Allergy Clin Immunol 110:341-348, 2002.
IgE, immunoglobulin E; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

Therapeutic and prophylactic use of large quantities of antibiotics is common in the production of beef cattle, swine, fish, poultry, and sometimes vegetables and fruits. Along with antibiotics, sodium and potassium bisulfites and metabisulfites are used as preservatives in foods. Sulfites have been used as antioxidants in the food and restaurant industry to prevent discoloration of vegetables (e.g., salad bars and avocado dips), fruits, and potatoes and to preserve fruit and vegetable juices. They are also used to prevent bacterial contamination and oxidation of wines, beers, and distilled beverages. Sensitivity to ingested sulfites has been well documented, especially among asthmatics.[12] Establishment of a particular foodstuff or preservative as the causative agent of anaphylaxis can be difficult.

Antibiotics

Allergic reactions to common antibiotics, such as benzylpenicillin, semisynthetic penicillin, and cephalosporins, are well documented; allergy to penicillin is perhaps the most commonly reported medication allergy. Because of their low molecular

www.ketabpezeshki.com 66485457-66963820

weights, these antimicrobials themselves do not possess antigenic properties (they are haptens). They become immunologically active (i.e., elicit an immunologic response) only after they bind to a "carrier" host protein. Although patients often report a history of penicillin allergy, this may not stand up to close scrutiny.[13] Studies have shown that up to 90% of individuals with a reported history of penicillin allergy can safely use penicillin; these individuals usually either are mislabeled as penicillin allergic or lose their allergy after years of avoidance.[14] Depending on the studies, the frequency of allergic reactions to penicillin varies from 0.01 to 0.05% (1 to 5 reactions per 10,000), with an anaphylactic reaction rate of less than 0.01% and a fatality rate of less than 0.002% (less than 1 fatality per 50,000 penicillin administrations).[15] Parenterally administered penicillin is responsible for most of the anaphylactic reactions. The extensive use of this drug in unsuspected sources such as foods, in which it is used as a bacteriostatic agent, may make it difficult to ascertain historically that penicillin is not the causative agent.

Cephalosporins share the β-lactam ring structure and side chains of the penicillins, and allergic cross-sensitivity has been incriminated in 1 to 8% of patients.[16] Patients who have urticaria or anaphylactic reactions after taking penicillin are approximately four times more likely to have an adverse reaction to cephalosporins. Even in this setting, the risk of an anaphylactic reaction to cephalosporins is still less than 0.1%, and the first dose of cephalosporin can be administered orally under medical supervision.[17]

Insect Stings

Hymenoptera venoms and fire ant stings are responsible for significant anaphylactic morbidity and mortality.[18] The Hymenoptera venoms are complex mixtures of pharmacologically and biochemically active substances. Honeybee venom contains hyaluronidase, phospholipase A, and other peptides. Yellow jacket venom contains not only phospholipases A and B and hyaluronidase but also kinins. Hornet venom contains acetylcholine in addition to those typical peptides. Fire ant venom is mostly a nonproteinaceous alkaloid suspension containing phospholipase A and hyaluronidase.

Stinging Hymenoptera insects affect up to 13.6 million Americans annually (c. 1999), accounting for approximately 50 to 100 deaths annually.[19] Allergic sensitization to Hymenoptera has been reported in 0.4 to 4% of the general population. The principal offenders (in decreasing order of frequency) are yellow jackets, honeybees, wasps, and yellow and bald-faced hornets. The imported fire ant has become a significant pest responsible for anaphylaxis, spreading from the Atlantic and Gulf coasts inland.[20] The introduction of killer (Africanized) bees in Brazil and their subsequent northern migration make them a significant cause of sting-induced anaphylaxis in areas of Texas, Arizona, and the southwestern United States.[21]

Other Agents

Latex and Medical Products. Latex allergy refers to sensitivity to the proteins or chemicals contained in the latex products. The sensitivity reaction can be delayed (type IV) contact dermatitis or an immediate hypersensitivity (type I) reaction (Box 119-3). The most common symptoms of latex allergy include allergic urticaria, rhinitis, conjunctivitis, and occupational asthma. Although latex allergy used to be more common, with the institution of nonpowdered gloves and nonlatex gloves in hospitals, anaphylactic reaction from latex has become an uncommon event.[22] Anaphylactic reactions have also occurred against ethylene oxide (ETO), which is used to sterilize hemodialyzers. ETO can bind with human proteins such as human serum albumin (HSA), rendering the ETO-HSA complex allergenic.

Box 119-3 Gell and Coombs Classification of Immune Reactions

Type I: Immediate Hypersensitivity
Binding of multivalent antigens to IgE on the surface of mast cells and basophils leads to degranulation of mediators. In previously sensitized individuals, the reaction develops quickly (minutes). This type of hypersensitivity reaction is seen in allergic diseases (e.g., hay fever, allergic asthma, urticaria, angioedema, and anaphylaxis). *Anaphylactoid reaction* refers to the direct release of preformed mediators of mast cells independent of IgE.

Type II: Cytotoxic Antibody Reaction
Antibody (IgM, IgG) binding of membrane-bound antigens leads to cytotoxicity and cell lysis of cells through the complement or mononuclear cell system (macrophages, neutrophils, and eosinophils). This type of reaction is seen in transfusion reaction and Rh incompatibility.

Type III: Immune Complex–Mediated Reaction
Binding of antibody (IgM, IgG) to antigens forms soluble immune complexes, which are deposited on vessel walls, causing a local inflammatory reaction (Arthus reaction) leading to inflammation and tissue injury. This type of reaction is seen in systemic lupus erythematosus and serum sickness (after antithymocyte globulin administration).

Type IV: Cell-Mediated Delayed Hypersensitivity
Sensitized lymphocytes (T_H1 cells) recognize the antigen, recruit additional lymphocytes and mononuclear cells to the site, and start the inflammatory reaction. No antibodies are involved. This type of reaction is seen in contact dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Anesthetic Drugs. Local anesthetics produce occasional adverse reactions.[23] Most of these reactions are not allergic in nature but are related to a direct effect of the medication. True allergic reactions are uncommon and are most commonly seen with local anesthetics from the ester family (e.g., procaine, tetracaine, and benzocaine). Allergic reactions to local anesthetics belonging to the amide family (e.g., lidocaine, bupivacaine, mepivacaine, and dibucaine) are rare. Multidose vials of lidocaine contain the preservative methylparaben, which belongs structurally to the ester family. This preservative has been implicated in allergic reactions in patients with a history of previous lidocaine hypersensitivity.[24] Only pure lidocaine (without the methylparaben preservative) should be used in intravenous applications (as in Bier's block).

Vaccines. Anaphylactic reactions have occurred after the administration of egg embryo–grown vaccines, including the combined measles, mumps, and rubella (MMR), yellow fever, and influenza vaccines. Patients who are able to tolerate eggs orally are likely to tolerate the vaccines.

Blood Products. Anaphylactic-type reactions are an uncommon complication of the administration of whole blood and immunoglobulins. The fixation of antibodies to formed elements such as red blood cells, platelets, and leukocytes and soluble components activates the complement system. This is particularly relevant in IgA-deficient patients exposed to multiple transfusions, who may have produced antibodies to IgA in previous transfusions. With subsequent transfusions, an antigen (IgA)–anti-IgA antibody (IgG) immune complex forms, leading to subsequent activation of the complement cascade.

Opiates. Many of the opioid analgesics can cause anaphylactic reaction through a direct histamine release mechanism, although some are IgE mediated. It is unclear how much cross-sensitivity is present among these agents.[25]

www.ketabpezeshki.com 66485457-66963820

Box 119-4 A Standard Treatment Protocol for Patients with a History of Radiocontrast-Induced Anaphylaxis

Prednisone 50 mg by mouth given 13 hours, 7 hours, and 1 hour before the procedure
Diphenhydramine 50 mg intramuscularly given 1 hour before the procedure
Consider ephedrine 25 mg by mouth given 1 hour before the procedure
Consider an H_2 antagonist such as ranitidine 300 mg by mouth given 3 hours before the procedure

Modified from Lieberman P: Anaphylaxis. Med Clin North Am 90:77, 2006.

Radiocontrast Media. Radiocontrast media (RCM) represent an important class of drugs that can cause an anaphylactic reaction. Approximately 10 million radiologic studies using RCM are performed in the United States annually. Anaphylactic reactions to RCM are largely idiosyncratic, occur within minutes of infusion, and are independent of the dose. The pathophysiologic mechanism of anaphylactic reactions to RCM is unknown, but it is believed to be nonimmunologic. Suggested mechanisms include direct histamine release, alternative complement pathway activation, and activation of the contact system. Risk factors for an anaphylactic reaction include a previous adverse reaction to RCM, a history of atopy or allergic disease, asthma, and certain medications. A history of allergy to fish or shellfish is not a contraindication to the use of RCM, nor does it increase the risk of an adverse reaction to RCM.[26] Clinically, the risk for severe adverse reaction is 0.16% with ionic contrast materials and 0.03% with nonionic contrast materials. The death rate from RCM reactions is estimated at 1 to 3 per 100,000 administrations of contrast material.[27] Protocols have been developed to minimize risks of a serious allergic reaction in patients who have had a previous adverse reaction to RCM but who still require additional radiographic studies with contrast agents (Box 119-4).

Aspirin and NSAIDs. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are believed to cause anaphylaxis (or anaphylactoid reaction) through interruption of arachidonic acid metabolism.[28] The incidence of anaphylaxis to aspirin and NSAIDs varies widely, depending on the population (healthy, atopic, or those with nasal polyps). One study estimated the incidence as 2.1 anaphylaxis cases per 100,000 exposed patients.[15] Desensitization protocols have been suggested for cardiovascular patients with a history of aspirin allergy.[29] For aspirin-induced cutaneous disease, an aspirin desensitization protocol that can be used for cardiovascular patients in the ED is to administer aspirin every 15 minutes, starting with 0.1 mg, up to 325 mg at 135 (FD&C Yellow No. 5), may also cause anaphylaxis through modulation of arachidonic acid metabolism.[31]

Immunotherapy Drugs. Allergen extracts are commonly used in skin testing and in immunotherapy (also known as hyposensitization or desensitization).[32] Exposure to therapeutic pollens, by injection or inhalation, can result in local allergic or systemic anaphylactic reactions. High-dose therapy, too frequent administration, or inadvertent intravascular injection increases the risk of anaphylaxis with immunotherapy.

Steroids. Although corticosteroids are used in the management of acute allergic syndromes and anaphylaxis, adverse reactions to these medications have been observed after parenteral administration.[33] Skin testing may demonstrate the specific class of steroids responsible for hypersensitivity, and substitution of a different class should be considered.

Exercise (Physical)–Induced Anaphylaxis. Thermomechanical and physical factors (heat and cold), especially exercise, have increasingly been recognized as etiologic agents in certain anaphylactic-like incidents.[34] The mechanism is unclear, but release of mediators from mast cells and basophils has been implicated. Patients with exercise-induced anaphylaxis are generally dedicated athletes who may have a personal or family atopic history. Exercise-induced anaphylaxis has been demonstrated in some cases to depend on previous ingestion of food to which the patient may be subclinically sensitive. Provocative foods, if identified, should be avoided. Patients should discontinue the exercise at the onset of rash or pruritus. When exercise is continued beyond this point, clinical deterioration is likely in susceptible individuals. Prophylactic treatment with an antihistamine as a single agent or in combination with other agents may be helpful. Avoidance of precipitating factors, modification of exercise, and use of a self-injectable epinephrine kit are recommended for patients with exercise-induced anaphylaxis.

Idiopathic Anaphylaxis. In the United States, approximately 20,000 to 47,000 patients annually see allergists for signs and symptoms of idiopathic anaphylaxis (IA).[35] The diagnosis of IA is made only after extensive evaluation by the allergist. Although IA may be life-threatening, it is usually responsive to conventional therapies, including antihistamines, sympathomimetics, and especially prednisone.[36] Some cases of IA may appear to be caused by the act of kissing but are in fact caused by food or conversion disorders.[37] The overall prognosis for IA is good, but certain patients may experience recurrent IA despite intensive prophylactic therapy. Sometimes, IA can represent "progesterone" anaphylaxis.[38] Women suffering from this disorder may present with recurrent episodes of anaphylaxis that are temporally related to the menstrual cycle. Other patients may have anaphylactic reactions to injection of medroxyprogesterone or luteinizing hormone–releasing hormone.

PRINCIPLES OF DISEASE

Because allergy is intimately related to immunology, a brief review of immunology is included in this chapter. Immunologic responses to *antigens* in humans are coordinated by two systems: the ancient *innate* immune system, which humans inherited from invertebrates; and the recently evolved *adaptive* immune system, which is present in humans and vertebrates (Fig. 119-1). The innate immune system is considered the first line of defense, characterized by its nonspecific but rapid responses to offending agents or microbes. Its effector components include resident cells (epithelial cells, mast cells, macrophages, dendritic cells, antimicrobial proteins), infiltrative cells (natural killer cells, neutrophils, monocytes, dendritic cells), and various proteins (antimicrobial peptides, complements, cytokines, pathogenic pattern recognition receptor [PRR] system). Encoded in the germline, PRRs can recognize pathogen-associated molecular patterns (PAMPs) extracellularly or intracellularly. PAMPs are evolutionarily conserved molecular patterns that are present in microbes but not in humans (except in mitochondrial DNA).[39] On exposure of the human host to these PAMPs, the PRR and subsequently the innate system and the inflammatory cascade are activated, leading to the clearance of dangerous PAMPs.[40] The innate system responds to the danger signals rapidly and nonspecifically, whereas the adaptive immune system takes time for the antigen-specific cells (B and T cells) to amplify through a process known as *clonal expansion* to mount a specific immune response. In contrast to the innate system, the adaptive immune system is characterized by the delayed response, immune memory, enormous diversity, and exquisite specificity. The effector components of the adaptive system include B and T lymphocytes and cytokines. T and B cells are capable of recognizing myriad antigens through a vast library of antibodies and receptors (up to 10^{15}). This diversity is accomplished by somatic rearrangement of fewer than 400 genes.[41,42]

www.ketabpezeshki.com 66485457-66963820

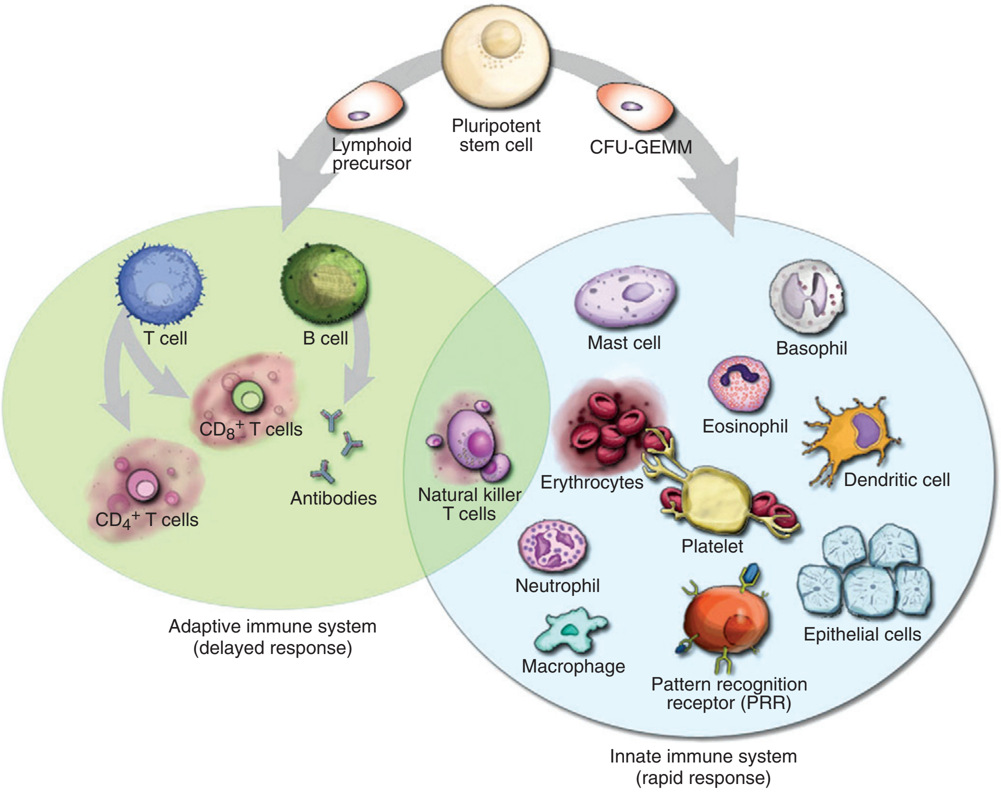

Figure 119-1. Developmental pathways of the immune and hematopoietic systems. *CFU-GEMM,* colony-forming unit for granulocyte, erythroid, myeloid, and megakaryocyte.

Development of the Immune System and Mechanism of Immune-Mediated Injury

The adaptive and innate immune systems originate from the common pluripotential hematopoietic stem cells, which are derived from the yolk sac and later reside in the bone marrow. These stem cells differentiate and develop into the lymphoid precursor cells and the colony-forming unit for granulocyte, erythroid, myeloid, and megakaryocyte (CFU-GEMM) stem cells. The lymphoid precursor cells differentiate into bursa-equivalent lymphocytes (B cells), thymus-derived lymphocytes (T cells), and natural killer cells. The CFU-GEMM cells develop into mast cells, basophils, and others (see Fig. 119-1). When the host encounters a foreign antigen, the cellular components of the adaptive immune system interact with the cellular and protein components of the innate immune system to mount a concerted defense aimed at neutralization of the antigen.

T-Cell Development

Lymphoid precursor cells migrate from the bone marrow into the thymus, where they continue their ontogeny.[43] Under regulation by cytokines and cell-cell interaction, these precursors undergo gene rearrangement and positive and negative selection. In the process, T cells acquire the T-cell antigen receptors and various surface markers. Two types of T cells mature and come out of the thymus: $CD4^+$, also called helper T cells (60-70%), and $CD8^-$, also called suppressor T cells (30-40%). Depending on the type of cytokine produced, T helper cells differentiate into type 1 helper cells (T_H1) and type 2 helper cells (T_H2), with opposing activities. Whereas T_H1 cells inhibit IgE production and IgE isotype switching, T_H2 cells stimulate IgE production and IgE isotype switching. The balance of these stimulatory and inhibitory activities of the T_H1 and T_H2 cells is believed to determine an individual's propensity to develop allergic disease or atopy and may help explain the increased prevalence of allergy in urbanized and Western societies in the past three decades. Early in utero and soon after birth, naïve T lymphocytes in the infant's immune system are dominated by the allergy-prone T_H2 cells and their associated cytokines (interleukins 4, 5, and 13). These cytokines are important inducers for production of IgE antibodies. Later, during infancy through early childhood and adolescence, the nonatopic infant's immune system gradually shifts from this allergy-prone T_H2 environment to an allergy-protective T_H1 environment. The cytokines associated with this T_H1 environment include interleukin-2 and interferon-γ. This shift is thought to be caused by the continual exposure of the young individual's immune system to allergenic stimuli from the surrounding environment, mainly microbes. Features of Western lifestyles, such as changes in infant diets, widespread use of antibiotics, smaller family size, and cleaner childcare, are believed to reduce this stimulatory antigenic exposure in an individual's early years, leading to an environment in which the immune system is dominated by a persistent allergy-prone T_H2 system (the hygiene hypothesis). This imbalance between the two immune systems supposedly ultimately leads to atopy and thus an allergy-prone population.[44]

B-Cell Development and Immunoglobulins

B-cell ontogeny is divided into antigen-independent and antigen-dependent stages.[43] During the antigen-independent stage, B cells mature in primary lymphoid organs (bone marrow and fetal liver), where they undergo gene rearrangement in a stochastic

www.ketabpezeshki.com 66485457-66963820

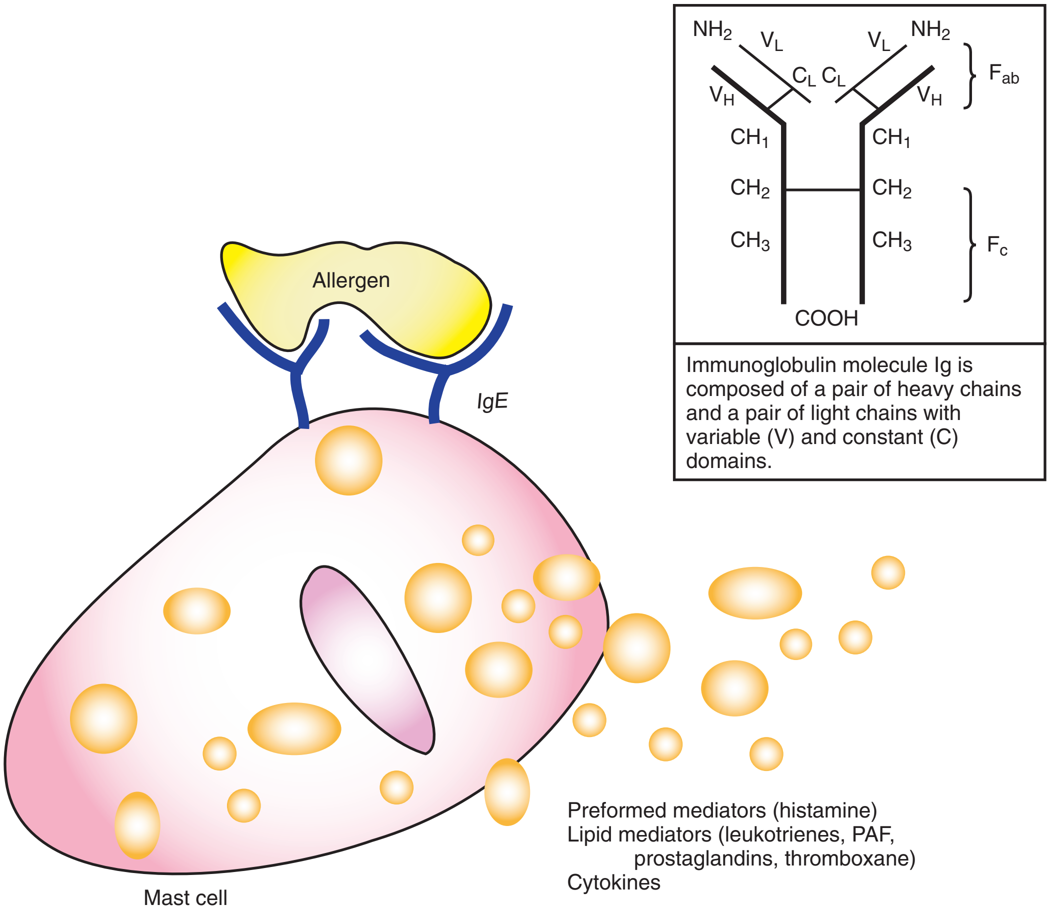

Figure 119-2. Activation of mast cells with degranulation of mast cell mediators by antigen cross-linking of adjacent immunoglobulin E (*IgE*) on the cell surface. *PAF,* platelet-activating factor.

manner and acquire various surface markers. Later during the antigen-dependent stage in the secondary lymphoid organs (lymph nodes and spleen), B cells differentiate into memory B cells and plasma cells and are ready to secrete immunoglobulins. Throughout B-cell ontogeny, B-cell maturation, isotype switching, and immunoglobulin production are driven by activated T cells, cytokines, and interaction with antigen and bone marrow stromal cells.

Immunoglobulins are protein molecules composed of two identical polypeptide heavy chains and two identical polypeptide light chains, covalently linked by disulfide bonds (Fig. 119-2). The heavy (H) chains have one variable domain, V_H, and three or four constant domains, C_H. The light (L) chains have one variable domain, V_L, and one constant domain, C_L. The variable domains of the heavy and light chains together form a pair of identical antigen-binding sites and with the adjacent constant heavy domain pair make up the Fab (antibody-binding fragment) region of the immunoglobulin molecule. The remaining constant domains of the heavy chains together form the Fc (crystallizable fragment) region of the immunoglobulin molecule. The Fc binds to the surface receptors of effector cells, such as mast cells, B cells, or macrophages. There are five isotypes or classes of immunoglobulins, IgG, IgA, IgM, IgD, and IgE; isotype IgG has four subclasses (IgG1, IgG2, IgG3, and IgG4), and IgA has two subclasses (IgA1 and IgA2). The body usually produces IgM antibodies when it first encounters an antigen. Repeated antigenic exposure, however, may cause the constant region of the IgM to switch to another class (IgA, IgG, or IgE), a process also known as isotype switching. Isotype IgE (and IgG4) is the most important antibody in the pathogenesis of allergic disease and anaphylaxis.

Classification of Reactions

The term *allergy* is commonly used to describe clinical illnesses produced by excessive immune responses by a normal immune system to otherwise innocuous allergens. In this chapter, we adapt the classic Coombs and Gell classification to categorize these hypersensitivity reactions (Box 119-5).

Type I reactions (immediate hypersensitivity) are IgE mediated and account for most allergic and anaphylactic reactions observed in humans. Exposure to sensitizing allergens causes mediators from mast cells and basophils to be released through both IgE-dependent and direct mast cell degranulation (IgE-independent) mechanisms. Rhinitis caused by ragweed pollen and anaphylaxis caused by foods are examples of the IgE-dependent mechanism; anaphylactic reaction to aspirin is an example of the IgE-independent mechanism.

Type II reactions (cytotoxic) denote antibody-mediated cytotoxic reaction. Complement-fixing IgG (or IgM) engages cell-bound antigen, activating the classic complement pathway and leading to the fixation of membrane attack complexes on the cell surface and subsequent cell lysis. In the process, anaphylatoxins C3a and C5a cause mast cell mediators to be released, producing the same clinical syndrome seen in allergic anaphylaxis.

Type III reactions (immune complex) are IgG or IgM complex mediated. Circulating soluble antigen-antibody immune complexes migrate from the circulation to be deposited in the perivascular interstitial space, thereby activating the complement system. Anaphylactic reactions to blood transfusions and blood component therapy, including serotherapy (immunoglobulin administration), are examples of the overlap of type II and type

Box 119-5 Clinical Criteria for Diagnosis of Anaphylaxis

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, pruritus or flushing, swollen lips-tongue-uvula) *and at least one of the following:*
   a. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
   b. Reduced BP or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
2. Two or more of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen for that patient:
   a. Involvement of the skin-mucosal tissue (e.g., generalized hives, itch-flush, swollen lips-tongue-uvula)
   b. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
   c. Reduced BP or associated symptoms (e.g., hypotonia [collapse], syncope, incontinence)
   d. Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP after exposure to known allergen for that patient (minutes to several hours):
   a. Infants and children: low systolic BP (age specific) or greater than 30% decrease in systolic BP*
   b. Adults: systolic BP of less than 90 mm Hg or greater than 30% decrease from that person's baseline
